## 1. EXECUTIVE SUMMARY

1. A fracture dominated geothermal resource with a base temperature of 190-200°C has been identified in the South Reservoir area of the Meager Creek Project. Geothermal fluids have been intersected in all three deep exploratory wells, although the host rocks are characterized by low overall permeability and porosity.
2. On-going temperature and flow testing on well MC-1 have demonstrated the viability of commercial steam production from the Meager Creek resource. A 20 kW steam turbine was installed to further the scope of the test program and the understanding of the nature of the resource.
3. The results of flow tests on well MC-3 have demonstrated significant production potential from a depth of approximately 3000 m. However, because of the configuration of the well liner, the production zone cannot be effectively isolated and an accurate production assessment is difficult to ascertain.
4. Although the outlook for commercial development of the Meager Creek geothermal resource is optimistic, decreased load forecasts and current economic constraints have put a halt to B.C. Hydro's involvement with the project. As economic

conditions become more favourable, Meager Creek may well prove to be a sound, environmentally acceptable source of electricity.

## 2. SUMMARY AND CONCLUSIONS

### 2.1 Summary

The testing and monitoring program conducted during 1983-85 advanced the knowledge base on the Meager Creek geothermal system substantially.

#### 2.1.1 Temperature Measurements

A total of fifteen temperature surveys were conducted on the three deep exploratory wells during 1983-84. In addition to ongoing monitoring of the static wells MC-2 and MC-3, valuable temperature data from the producing well, MC-1 were obtained (Appendix A).

Inaccessible since test production was begun in November, 1982, the three temperature surveys conducted on well MC-1 during 1983 were particularly informative. The temperature profiles indicate that fluid is produced from approximately 1400 m depth, and rises isothermally to about 200 m. At this point, the fluid begins to boil and the apparent temperature drops markedly towards

surface. A possible cool inflow is indicated by a slight downward inflection in the curve at a depth of 150 to 250 m. Temperatures at the bottom of the well remain in the 230 to 235°C range, indicating that testing over the course of the year has not noticeably affected the pre-production thermal regime. Two later surveys in 1984 were obstructed at a depth of approximately 700 m by the liner hanger. The information obtained in the upper portion of the hole indicates a continued warming trend.

Three temperature surveys in well MC-2 (commencing in July, 1983) indicate a minor temperature rise of 3 to 5°C over the long static time since November, 1982. The temperature profile is indicative of conductive cooling over most of the length of the drill hole with minor inflections at 1200 and 2300 m. The well remained dormant through 1984.

As with MC-2, well MC-3 demonstrated a small, long term temperature rise since November, 1982. Nine temperature surveys conducted during late 1983 showed a significant temperature increase at depths below 3000 m, prompting a flow test on the well. Rising temperatures were postulated to be a reflection of increased permeability at the No-Good Zone intersection, and that an airlift from depths below 2500 m would stimulate flow from this previously untested zone. A later temperature

survey in October, 1984 confirmed that the warming trend continues.

### 2.1.2 Flow Testing and Monitoring

Well MC-1 has been under test production since November, 1982. During 1983-85, the wellhead pressure and discharge rate were measured daily up to October 1984 and discharge fluids were sampled and assayed for standard chemical components regularly (Appendix C).

Pressure and flow rate are regulated by adjustments to the valve system on the wellhead, thereby controlling the depth of the flashpoint within the well bore. An optimal pressure, established over the previous flow record, of 200 to 220 kPa has been maintained whenever possible. This pressure allows a flow rate of approximately 15 to 17 tonnes/hr of geothermal fluid to discharge from the outlet. The discharge comprises approximately 15% steam and 85% low salinity "brine" at a temperature of 96°C.

Periodically, the well bore becomes plugged with carbonate-silica scale precipitated from the geothermal fluid. Although pressure maintenance at the wellhead has proven to be the most effective scale control procedure, mechanical scale removal

has been required on a number of occasions. Well pressure records show periods where the well has been choked by excessive precipitation of carbonate scale, and pressure and flow rates cannot be maintained. At these times, the well bore has been cleared by a specially designed scale hammer. The hammer is dropped onto the scale blockage, chipping away the soft accretion and allowing improved flow. The most effective tool for scale removal, however, appears to be a small drilling rig. A B.C. Hydro diamond drill Boyles 56A complete with BOP was employed to ream out the wellbore following the May, 1984 blockage. Since that time, well performance has been improved substantially, and scale accumulation has been minimal.

### MC-3

Interest in a possible producing zone in MC-3 was spurred by a 5 to 8°C temperature increase throughout the well. Particular consideration was given to the No-Good Zone, a structure of known permeability at a depth of 3025 m.

A flow test entailing an airlift through endless tubing to a depth of 2500 m was conducted in early November, 1983. The airlift successfully stimulated flow from the No-Good Zone, producing wellhead pressures approaching 800 kPa although spontaneous discharge was maintained only for a period of approximately 20 min. Under the low

pressure conditions imposed by the airlift, cool ( $160^{\circ}\text{C}$ ) near surface waters were flowing into the bore faster than the discharge rate of fluids from the No-Good Zone. As such, the downflowing waters soon quenched the flow from the No-Good Zone, suppressing the high pressure discharge from depth. If however, the No-Good Zone can be effectively isolated from the near surface waters, well MC-3 may be a significant geothermal producer.

### 2.3 Conclusions

Based on testing and monitoring to date, there appears to be good potential for geothermal development of the Meager Creek site. Recent studies including temperature testing, geochemical analysis and test production strengthen earlier conclusions that a fracture dominated geothermal resource with a base temperature of approximately  $200^{\circ}\text{C}$  is present at Meager Creek.

Two primary targets were identified during exploration phases of the work at Meager Creek. These are the Meager Creek Fault Zone and the No-Good Zone, both situated beneath the present deep wellsite. Observations made during the testing and monitoring program conducted in 1983-85 have served to confirm these fault related structures as representing the best production potential to date.

The installation of a small, 20 kW steam turbine on producing well MC-1 has further demonstrated the potential for development of the geothermal resource for power generation. The production fluids appear to be relatively free of toxic elements, and calcium and silica contents are within acceptable limits. No extraordinary treatment of the geothermal production fluid should be necessary.

However, because of the current economic outlook and diminishing load requirements, it does not appear to be in B.C. Hydro's best interests to develop the Meager Creek geothermal potential at this time.

### 3. INTRODUCTION

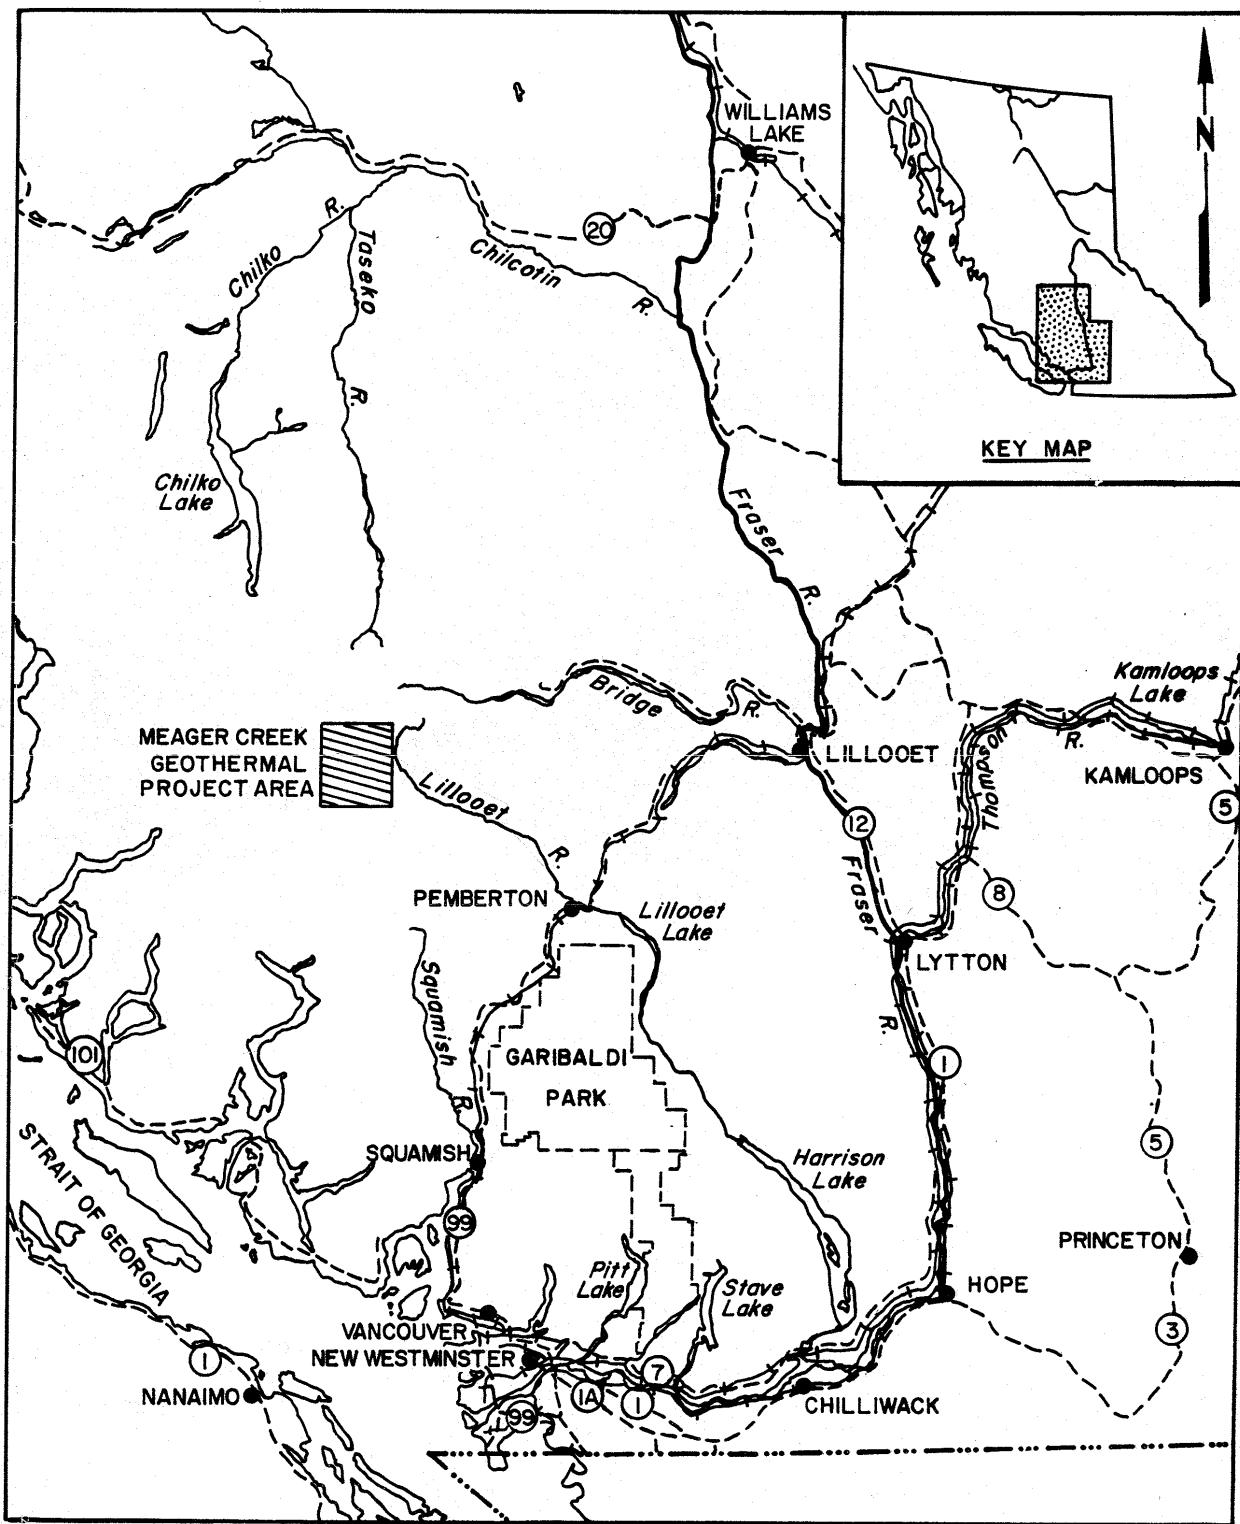

#### 3.1 Location and Access

The Meager Creek Project area is located approximately 200 km north of Vancouver in the rugged Coast Mountains of southwest B.C. (Figure 1). A good, gravel-surfaced logging road follows the Lillooet River valley for 50 km to the Meager area from the end of the paved highway at Pemberton Meadows. Flooding in early October, 1984 damaged several river and creek crossings although repairs are to be completed by Spring, 1985.

#### 3.2 Previous Work

Geothermal investigations at Meager Creek have been in progress since late 1973. B.C. Hydro became involved in 1974 with a small-scale diamond drilling project designed to evaluate the thermal characteristics of the Meager Creek Hotsprings and the surrounding area (Figure 2). Subsequent investigations identified and localized a potential resource area on the lower flanks of Pylon Peak, some 5 km upstream from the main vent of the Meager springs (B.C. Hydro, 1982).

Exploration culminated with the drilling of three, large diameter rotary holes during 1980 to 1982. Reaching depths of 3000-3500 m, the holes were

drilled to assess various targets identified in earlier studies. The program resulted in one well, MC-1 capable of long-term, sustained steam production. The two other wells, although unable to produce steam spontaneously in their present state, have been invaluable in the development of interpretive models for the geothermal reservoir.

### 3.3 Work Done in 1983/84 - 1984/85

Due to the poor economic climate and low electrical load forecasts, the geothermal drilling program was suspended in August, 1982. Since that time, activity at the Meager Creek Project has been restricted to testing and monitoring of the three deep exploratory wells.

MC-1, the first deep exploratory well has been in test production since November, 1982. Thermal fluid was discharged to a silencer/sePARATOR unit where wellhead pressure was recorded continuously with a clock-driven pressure gauge recorder and flow rate was measured and recorded daily up to October 84. In addition, periodic temperature surveys and chemical sampling are conducted to monitor changes in the thermal regime.

During the course of production, the MC-1 well bore became obstructed by a substantial carbonate scale

deposit. However, the blockage was successfully removed by mechanical means and further scale deposition has been inhibited by maintaining constant pressure at the wellhead.

MC-2 and MC-3 remained dormant for most of the 1983-85 period. Standing water levels in the wells were recorded regularly and periodic temperature surveys were run.

Increased temperatures and indications of improved crossflow at depth in well MC-3 prompted a flow test in early November, 1983. Continual airlifting for a period of 20 hr resulted in a series of discharges achieving peak pressures of 850 kPa. Because of the casing and liner configuration within the bore, however, a cooler surface water downflow quenched the flow approximately 20 min after the airlift was ceased.

In addition to the temperature monitoring, a small steam turbine was installed and tested on producing well MC-1. The turbine originally tested as a 80 kW binary unit in Imperial Valley, California, was rebuilt and redesigned as a 20 kW axial flow steam turbine. The 20 kW demonstration turbine was loaned to B.C. Hydro by the Electric Power Research Institute (EPRI) who monitored the collection and interpretation of test data. The unit performed well in a series of 25 tests conducted during the

summer 1984 and the results have provided a valuable insight into both the turbine design and the Meager Creek geothermal reservoir characteristics.

A study of the geochemistry of the Meager Creek geothermal field conducted by Dr J. Moore of the Earth Science Laboratory of the University of Utah Research Institute was completed in the summer of 1983. The results were reported in a paper presented to the Geothermal Resources Council 1983 Annual Meeting in Portland, Oregon. ~~A copy of this paper has been included in this report (Appendix D).~~ The geochemical evidence suggests that the fluids encountered in the deep wells have migrated from a hotter geothermal reservoir which has yet to be discovered.

Dr. Moore's studies continued in 1984 and these additional results were published in the paper, "Geologic and Geochemical Investigations of the Meager Creek Geothermal system, British Columbia, Canada" in January 1985. His analysis of the alteration mineralogy of drill core samples identifies at least two distinct periods of hydrothermal activity. Temperatures for the second period (that associated with the geothermal activity in the Meager Creek geothermal system) may be 50 to 150°C higher than those observed at present. He notes that extensive carbonate

precipitation which has sealed fractures in the upper portion of the reservoir may account for this temperature decline.

Dr. Moore is planning to continue his studies in 1985, detailing the origin and history of the thermal fluids at Meager Creek.

Another study, performed by Dr. M.M. Ghomshei, concentrated on the compilation and interpretation of geochemical data from water samples collected during earlier exploration stages at Meager Creek. The findings of the study tend to concur with Moore's conclusions that thermal waters encountered thusfar have probably been derived from a hotter geothermal reservoir nearby.

The Meager Creek wellsite was scheduled for abandonment by November, 1984 however, flooding in October stranded much of the equipment on site. The early onset of winter precluded further demobilization and all remaining equipment was winterized and was stored at the wellsite until road access was restored in May, 1985. The site was vacated by mid-November, although the dormant camp was visited regularly to guard against vandalism and snow damage. B.C. Hydro anticipates to vacate the site by October 1985.

## 4. RESULTS AND EVALUATION

### 4.1 Well MC-1

MC-1, the first deep exploratory well drilled at Meager Creek, was spudded in mid-July 1981 and completed four months later. The well intercepted geothermal water ascending along the Meager Creek Fault at a depth of 1600 to 1800 m and is capable of sustaining continual discharge of 195°C fluids from this zone.

Ongoing monitoring of production from well MC-1 was augmented by numerous other activities during 1983-85. Temperature surveys were run and the chemistry of the discharged fluid was monitored in order to become better acquainted with the geothermal reservoir characteristics.

By the spring of 1984, a small steam turbine had been installed on MC-1. The test program which saw Canada's first geothermal power production was conducted through the summer, 1984. Acquired test data are included in appendices of this report.

#### 3.1.1 Pressure and Flow Measurements

Well MC-1 was undergoing production testing since early November, 1982. The tests were conducted in order to determine the viability of long term production from the thermal reservoir. Continuous

production was to help ascertain the chemical signature and any chemical changes of the thermal water, the nature of the fracture system at depth and the long term effects of production on reservoir characteristics. The tests were also to indicate the severity of corrosion on surface equipment by the saline thermal waters.

Wellhead pressures were monitored continuously with a clock driven pressure gauge recorder mounted on a side-valve of the wellhead assembly. The chart was changed daily at which time the flow rate from the well was recorded. Flow was measured by means of a V-notch cut into the weir box of the separator/silencer unit. The total discharge from the well was estimated by adding 15% (to account for the steam fraction which escapes from the top of the separator/silencer) to the total liquid flow as calculated from the V-notch reading. The flow rate was recorded daily.

To inhibit scale deposition within the well bore, the master valve was kept slightly choked and the wellhead pressure was maintained at the highest level possible while allowing continuous flow. The geothermal fluid, saturated in carbonate and silica minerals, will deposit scale whenever high pressure or temperature conditions subside. When the fluid reaches its flashpoint, the pressure and

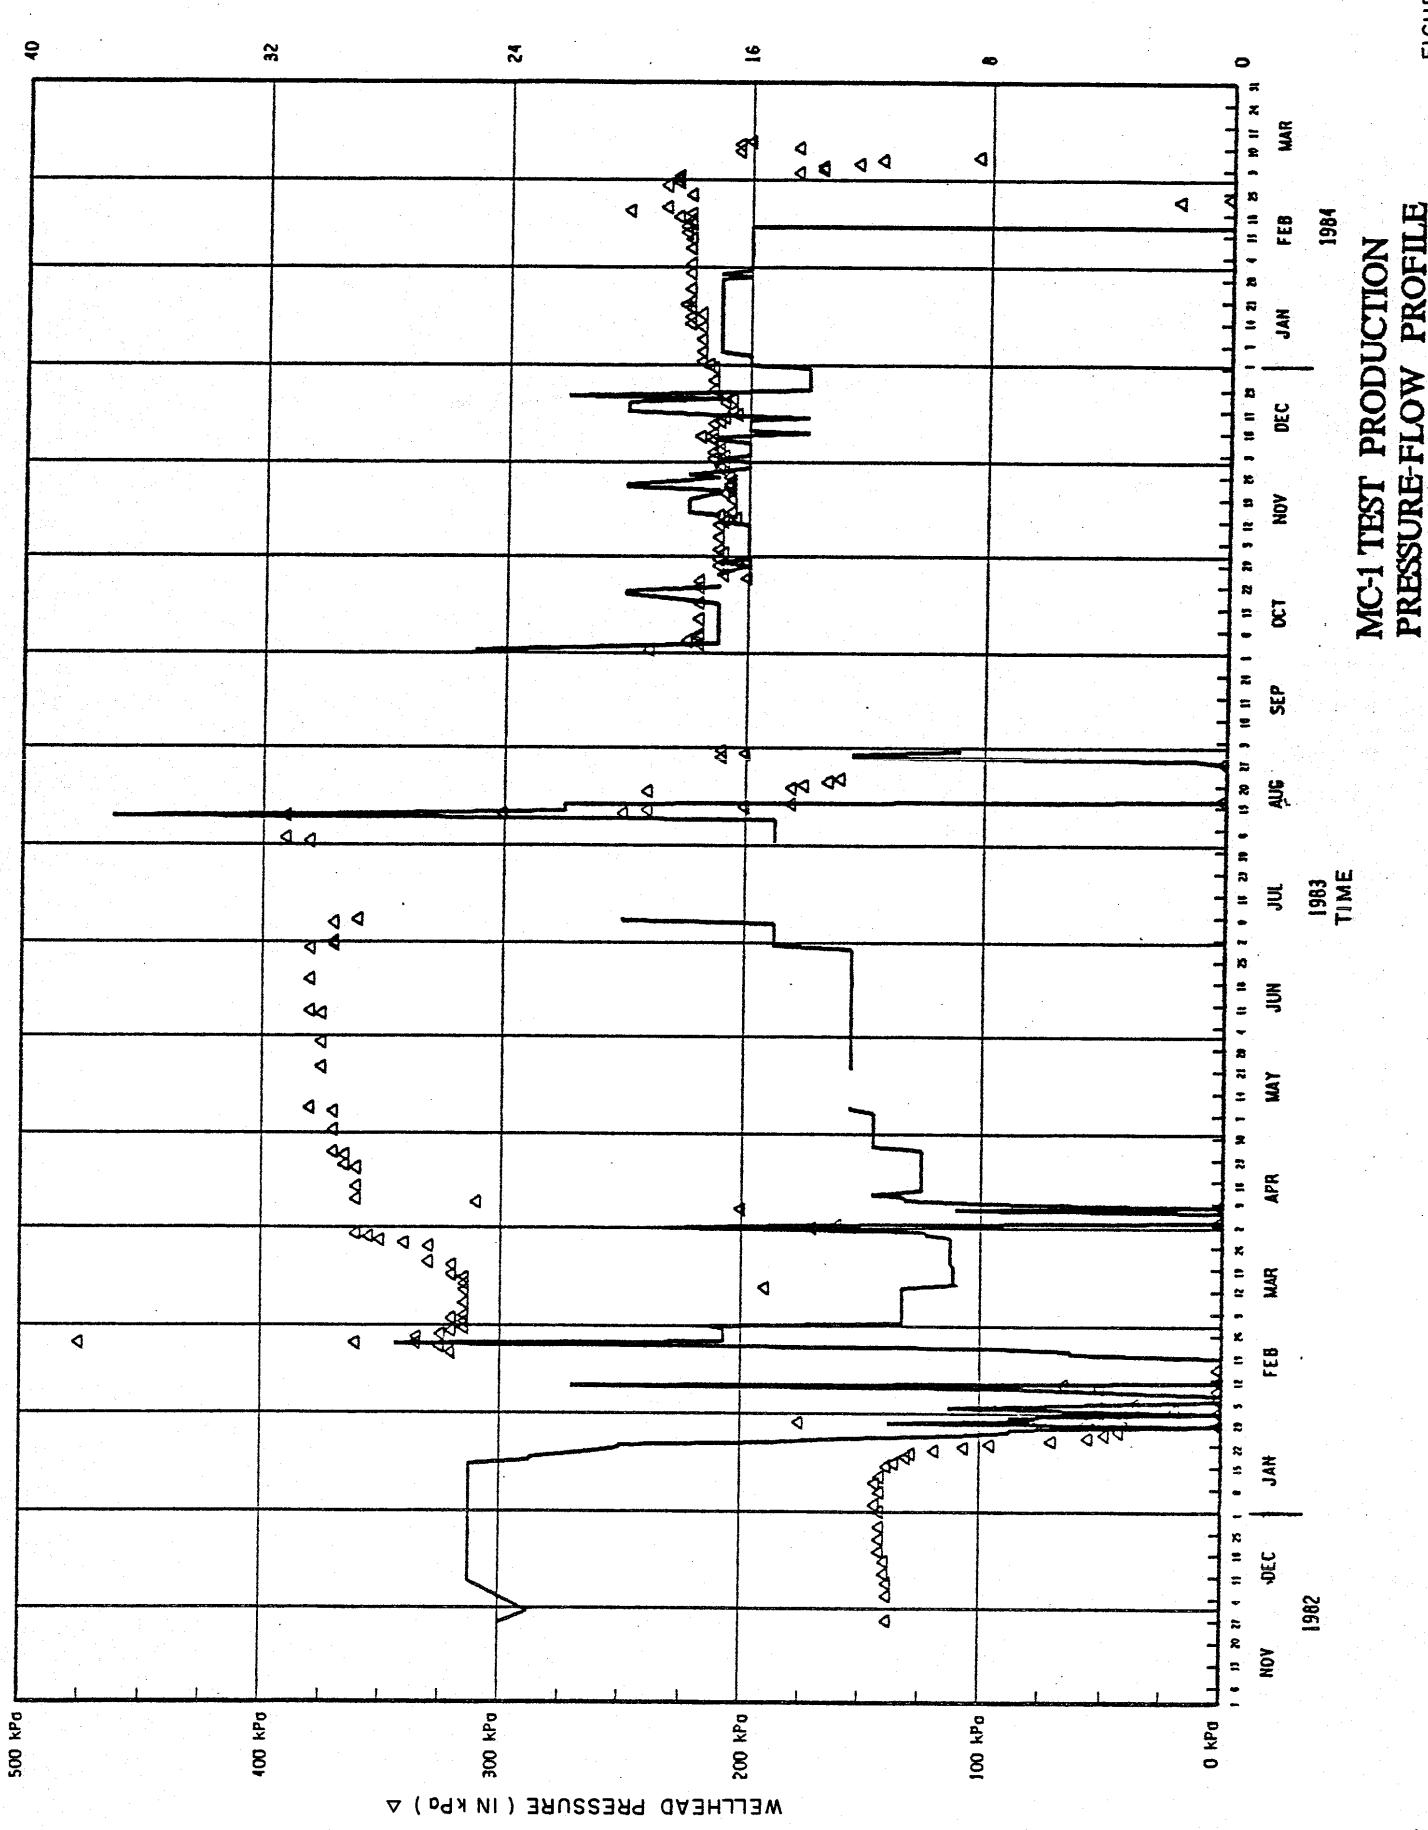

temperature drop drastically, and scale deposition occurs. By choking the master valve, the flash point could be manipulated to occur either at the outlet or within the wellhead, where scale can more easily be removed.

During test production, wellhead pressures were maintained at 200-220 kPa which resulted in an average flowrate of approximately 17 tonnes/hr (Figure 3). This is equivalent to approximately 4500 kW<sub>t</sub>, or 700 kW<sub>e</sub>.

#### Well Blockage

Figure 3 shows three periods where production was interrupted (January, 1983; September, 1983 and May, 1984). The January stoppage resulted from the deposition of a hard siliceous-carbonate scale in the wellbore at a depth of approximately 200 m. Precipitation of the scale occurred under lowered pressure conditions caused by conducting the production test at full discharge.

The blockage was temporarily removed by surging the well pressure. When flow was re-established, the discharge contained pebble-sized chunks of the scale as well as numerous fragments of torn rubber. Larger pieces of the carbonate scale contained in the discharge displayed a concentric pattern of radiating calcite/aragonite crystals up to 1 cm in

length. This configuration suggests an episodic deposition sequence rather than continual precipitation which might be anticipated from an established production test.

The rubber is believed to have been torn from the "centralizers" (the annular spacer placed between the drill string and the casing which is designed to minimize string vibration during drilling). Over several months of exposure to elevated temperatures and pressures, the rubber compounds became embrittled and the centralizers disintegrated. The rubber may have been a key component in formation of the blockage.

The blockage re-formed and again choked off flow from the well in mid-August. Various options for scale removal including acidization and carbon dioxide injection were considered. However, because of economic considerations, mechanical methods were eventually employed. The blockage was removed by hammering on the constriction with a specially prepared steel rod attached to a 1 cm diameter cable from the drill rig. The rod was drawn to the top of the wellhead with the "sandline" winch and was released, running freely into the hole and pulverizing the scale deposit. Although chemical treatment is available for scale control, the mechanical method proved simpler and more cost efficient given the localized scaling

problems in MC-1.

Decreased fluid production, again caused by scale deposition, began to interfere with turbine testing in May, 1984 and a diamond drill was used to ream the casing out with a six-inch reaming shell. A B.C. Hydro Force Construction Boyles 56A drill rig equipped with a bag-type blowout preventer was set up on log cribbing and specially designed elevated platform over the MC-1 wellhead. Using NQ rods and a reaming shell, the hole was cleared to a depth of 600 m. The operation was complete in approximately six days.

Well performance was significantly improved with this cleaning process showing approximately 15% higher pressures and 10% better flow over previous "clean bore" conditions. In addition, the recurrence of the scale deposition appears to be prolonged as the well showed no signs of production decrease until the completion of the monitoring program. The diamond drill rig remained on site should another clean-up operation be warranted.

#### 4.1.2 Temperature Measurements

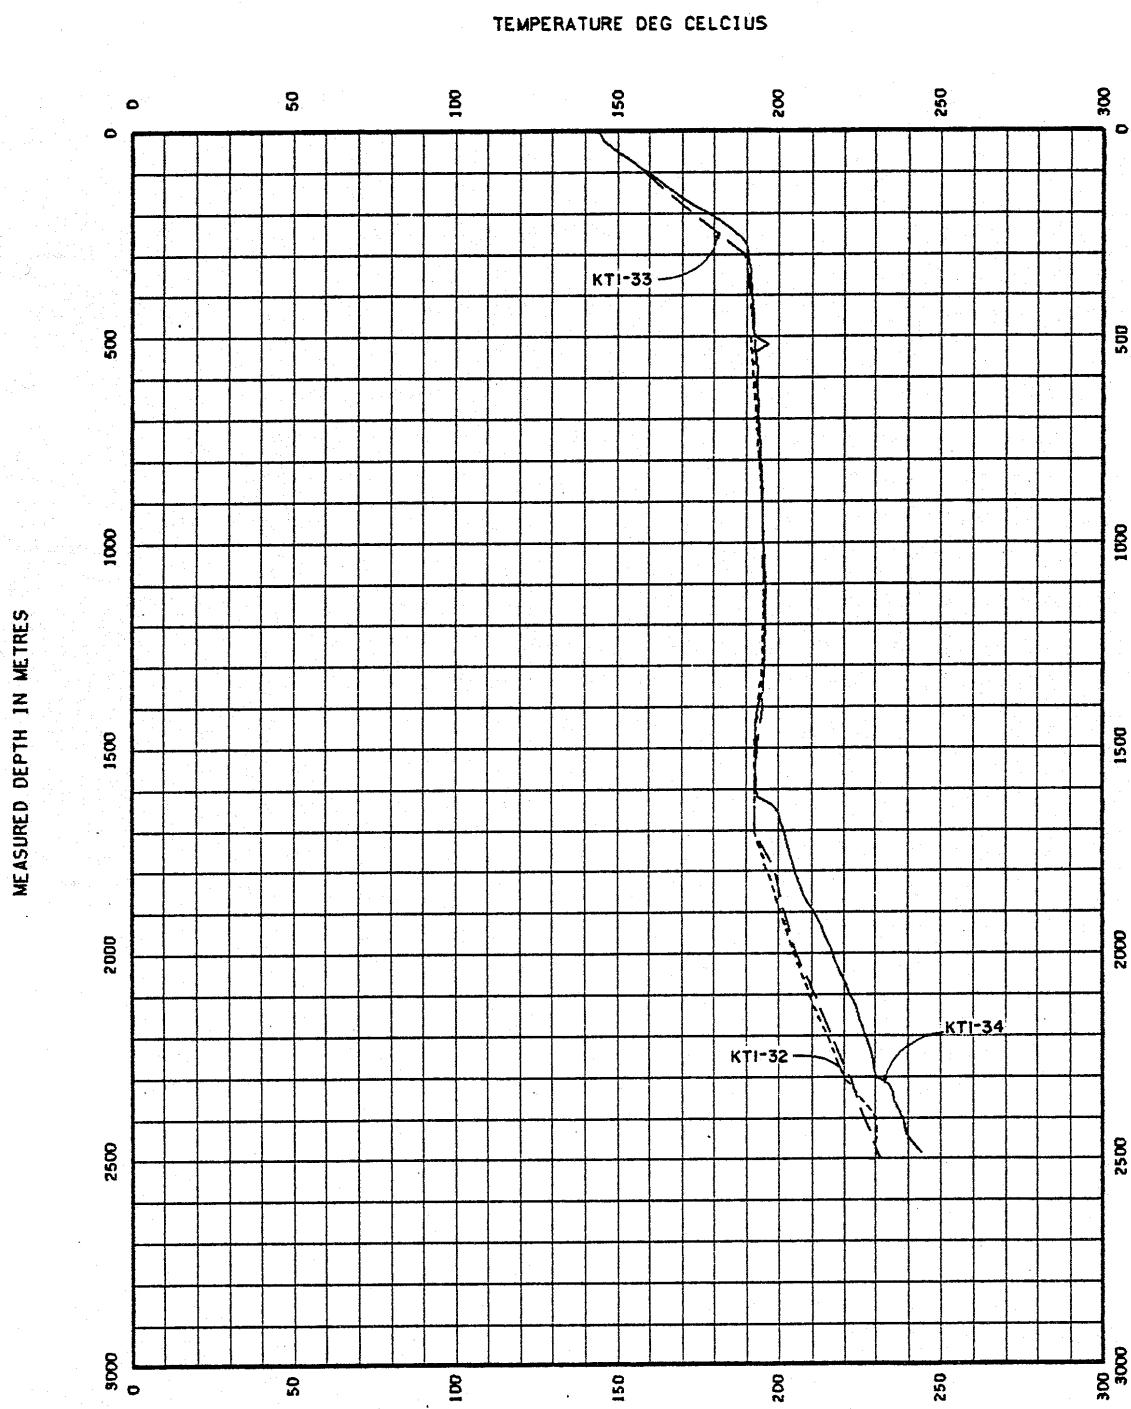

The MC-1 well was inaccessible since November, 1982, and the removal of the blockage in MC-1 again allowed data collection from the producing well to a depth of 2500 m. A total of three temperature

surveys (KT1-32 to KT1-34) were conducted. A final survey, KT1-35, was performed following the May, 1984 well bore clean-up and encountered an obstruction at a depth of approximately 700 m. The blockage is attributed to possible problems with the liner hanger at this depth.

Figure 4 shows a compilation of these surveys. The temperature profiles are characterized by a rapid, near surface temperature increase to a depth of about 250 m where the curves become almost isothermal. A slight depression of the temperature between depths of 1000 and 1400 m may indicate a cooler, surface water downflow and invasion of the well bore through the perforated liner.

Below a depth of 1400 m the fluid temperature increases sharply, indicating conductive heating within a static water column. Hot production fluids enter at a depth of 1300 to 1400 m and flow upwards isothermally to a depth of 240 m. Here, the fluid boils, separating into steam and liquid fractions. The two-phase fluid ascends to surface where the temperature drops to the ambient boiling point and releases the gas phase to the atmosphere via the silencer/sePARATOR unit.

However, because MC-1 has penetrated an unconfined thermal "aquifer", choking the main valve and increasing the wellhead pressure above a value of

MC-1 TEMPERATURE SURVEYS 1983-84

approximately 250 kPa simply causes the fluid to resume its original ascent path along the Meager Creek Fault.

Temperatures in MC-1 have been fairly constant although a slight warming trend has been noted. However, because no temperature data is available for the well between December, 1982 and September, 1983 it is unreasonable to compare pre-production temperature surveys with those taken under dynamic (production) conditions. However, comparison between KT1-32 (September, 1983) and KT1-35 (September, 1984) indicate an overall warming of 3 to 8°C/year and a decrease in the depth of the flashpoint to approximately 130 m.

#### 4.1.3 Well Chemistry

In addition to regular discharge sampling of MC-1, an EPRI mobile chemical sampling unit was brought to the site in early August, 1983. The portable lab (designed and operated by Rockwell International scientists on contract to EPRI) contains some of the most advanced and specialized geothermal sampling equipment available. EPRI brought the lab to Meager Creek in order to evaluate various chemical parameters of the

production fluid. In addition to ascertaining the severity of scale problems and corrosive properties of the fluid, the lab performed a variety of other evaluations including waste water and steam fraction toxicity determinations (Appendix B).

The analysis of periodic sampling of the production fluid from well MC-1 was reviewed by Dr. Morteza Ghomshei, working for the Meager Creek Project under a UNESCO post-doctorate fellowship. A paper entitled "Geochemical Evidence of Chemical Equilibria in the South Meager Creek Geothermal System" represents a summary of his findings (~~Appendix C~~). Raw water chemistry data and ionic strength vs. time interpretations are presented in ~~Appendix D~~.

#### 4.2 Well MC-2

The second deep exploratory well, MC-2, was drilled during the winter of 1981-82 and underwent moderate testing the following spring. Although temperatures in excess of 270°C were encountered, and the permeability of the host rock was higher than well MC-1, the flow was insufficient to allow for sustained fluid production at the time of testing. MC-2 intercepted the Meager Creek Fault at approximately 2100 m, however the fluid pressure at

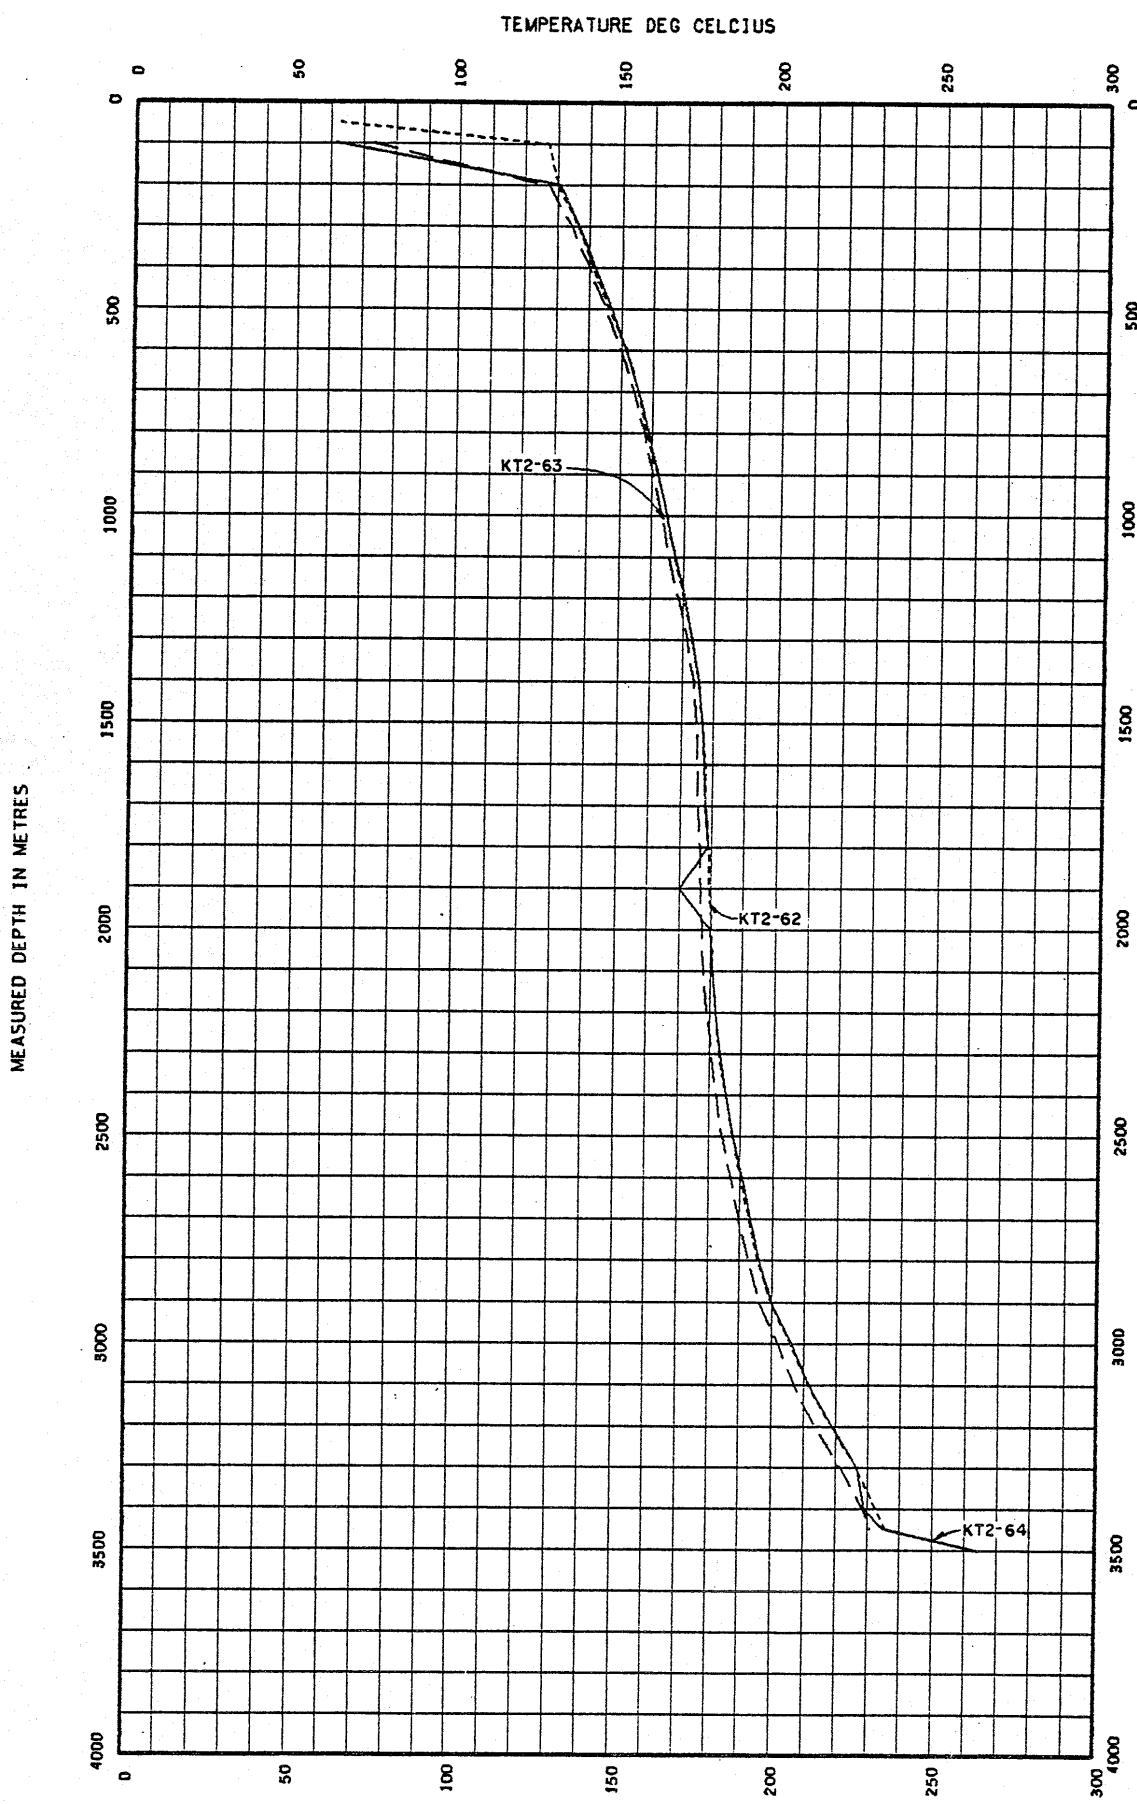

this depth within the zone is less than hydrostatic pressure of the static water column in the wellbore, effectively suppressing the "MC-1 style" production potential.

MC-2 remained largely inactive during the testing and monitoring program of 1983-84. A number of temperature surveys were run on the well during the summer and standing water level was monitored regularly. However, after difficulties in retrieving the temperature probe from the hole during a survey in late August 83, activity on the well has been minimal.

Three surveys were conducted (KT2-62 to KT2-64; Figure 6), and a significant increase in temperature was noted over comparable surveys performed approximately eight months earlier. A general increase of approximately 5°C was noted in the lower portion of the well. Also, the strong increase in the temperature gradient at a depth of 2300 m became more pronounced as the well experienced longer static times. Detailed temperature traverses did not identify any new, or previously undocumented water inflow zones.

#### Lost Equipment Recovery

A temperature probe was lost downhole during a survey run in late-August. Numerous attempts at

MC-2 TEMPERATURE SURVEYS 1983-84

FIGURE 5

recovering the lost probe were made with the wireline and specially designed fishing tools. However, the tensile strength of the wireline proved inadequate to pull the lost probe and tangled wire nest past the top of the liner hanger. Fishing for the tangle was continued with the "sandline", a 1 cm steel cable and winch assembly which is part of the on-site drill rig equipment. Again, a specially prepared fishing tool was attached and this time the temperature probe was recovered uneventfully. After a month in the hole, the case of the temperature probe had been covered with a fine coating of hard siliceous-carbonate scale and, apart from minor maintenance, the tool itself was fully functional. MC-2 is again clear to a total depth of 3503 m.

#### 4.3 Well MC-3

MC-3 is the third deep exploratory well drilled at Meager Creek. Spudded in June, 1982 and completed in early August, MC-3 showed signs of being the most successful well to date, with good permeability and high temperatures. However, formation damage from drill fluid invasion and the liner configuration have frustrated numerous attempts to prove the well's success.

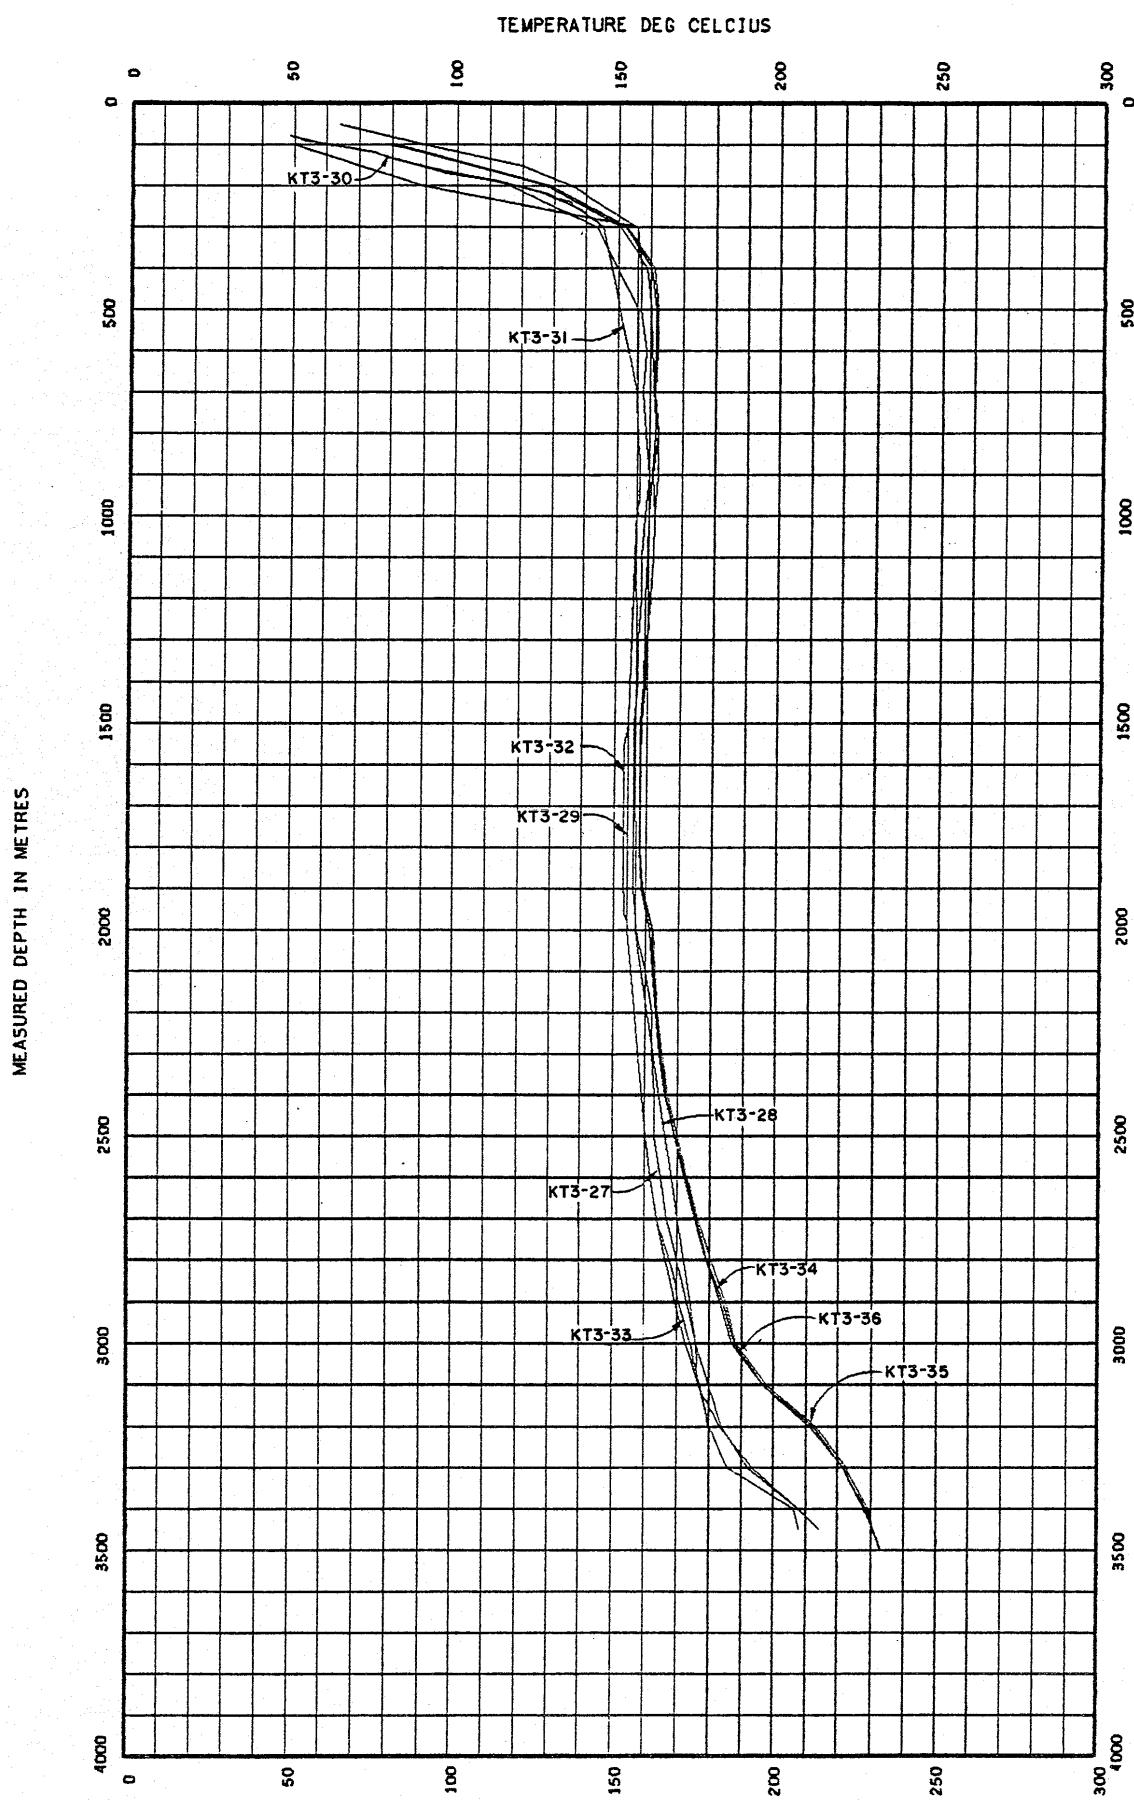

Well MC-3 received considerable attention during

the course of the monitoring and testing program of 1983-84. In addition to ten temperature surveys being conducted, MC-3 was the subject of an airlift and stimulation attempt in early November, 1983. The well, however, remained dormant through 1984 with several temperature surveys being conducted in late September.

#### 4.3.1 Temperature Measurements

Well MC-3 had a series of eleven temperature surveys run from mid-July, 1983 through late-September, 1984. Surveys KT3-27 to KT3-37 (Figure 8), as with MC-2, indicate a long term warming trend on the order of  $3-5^{\circ}\text{C}/\text{a}$ . The shape of the temperature profile remains essentially unchanged, comparing favourably with surveys conducted under similar conditions in late 1982 and indicating that downhole fluid flow conditions have not altered.

A long, static period (November, 1982 to July, 1983) has not affected the temperature profile between the depths of 200 and 2000 m. The isothermal temperature profile between the depths of 200 and 2000 m would indicate that some form of hydraulic communication exists between upper and lower production zones. Cooler,  $160^{\circ}\text{C}$  surface waters appear to be flowing down the well bore to the 2000 m depth.

MC-3 TEMPERATURE SURVEYS 1983-84

FIGURE 6

At the 2000 m depth, the fluid temperature increases slightly, indicating either a warm flow entering the hole and masking the effects of the cooler surface water, or the unsuppressed regional thermal gradient (ie. the water column below 2000 m is static).

At a depth of 3000 m, the temperature again makes a major upwards inflection. The increase in gradient at this point is attributed to a sizable inflow from the "No-Good Zone" encountered at a depth of 3025 m during drilling. At that time, lost circulation material was pumped into the hole to avoid excess fluid loss during drilling. However, the material did not wash out after drilling was ceased and the otherwise permeable zone remains clogged.

Temperature data recently collected near the bottom of the hole (3000 to 3500 m) reflect a significant increase in thermal activity, indicating that the lost circulation material may have been freed and hotter thermal fluids were being introduced to the wellbore.

#### 4.3.2 Flow Testing

The possibility of improved flow of thermal water approaching 230°C from the No-Good Zone prompted a

flow test on well MC-3. The test was conducted in early November, 1983 and achieved significant results.

#### Test Description

"Airlifting" is a common procedure used to stimulate production from oil and gas, and geothermal wells. Compressed gas is pumped into the hub of a spool of flexible steel ("endless") tubing while the tubing is slowly lowered into the hole. Gas rising through the static water column decreases its effective density and, consequently, the hydrostatic pressure. As a result, the 160°C fluid boils, forcing cooler water up the well bore ahead of the rapidly rising column of steam. In effect, the hole could be "pumped dry" to the depth of the end of the tubing as more of the column is vaporized.

In well MC-3, it was proposed that the endless tubing be run into the hole to the depth of the No-Good Zone. Given a sufficient pressure differential, the remainder of the lost circulation material would be expelled from the Zone, and hot water would be produced spontaneously.

The flow test on MC-3 entailed an airlift procedure at depth within the well bore. Endless tubing was brought to the site by NowSCO Well Services and

high-pressure air compressor pumps were supplied by International Air Drilling Services. This style of test had been attempted on MC-3 in October-November, 1982 although the tubing was not extended to the 2500 m depth at that time.

#### Observations

The airlift progressed smoothly for approximately 20 h while the tubing was lowered steadily into the hole. Care was taken not to over-pressure the tubing or compressors by slowing the endless tube feed rate while the hole boiled "dry" and the hydrostatic pressure subsided. During this time, hourly observations of wellhead pressure, discharge temperature, and flow characteristics were recorded. In general, a bell approximately 1 m diameter was formed at the outlet of the 6" (15 cm) diameter horizontal discharge pipe. The outlet temperature was consistently 93 to 97°C, near the boiling point under ambient atmospheric pressure.

While at a depth of approximately 2300 m, the pressure suddenly rose, and the discharge increased. Due to the concurrent equipment breakdown the compressors were stopped and the tubing was partially withdrawn. The well discharged a steam bell approximately 3 m in diameter. The flow was sustained for a period of about 20 min and pressures approaching 850 kPa were

recorded on the pressure gauge at the wellhead. When the flow stopped, the tubing was again pressurized up and lowered to a depth of 2400 m to iterate the results. Again, the well started to flow at about 700-800 kPa for 20 min after the air compressors had been shut down. Although, this process was repeated five times, the flow failed to sustain, choking itself off after about 20 min in each instance.

Following completion of the airlift, a temperature survey was attempted. However, the probe could not be lowered past a depth of 900 m. Apparently, the probe was catching on the liner hanger, although later attempts at the temperature survey did manage to pass the 900 m mark, and access the bottom of the hole.

#### Evaluation

The twenty minute, high pressure surges from MC-3 are an extremely encouraging indication of the producibility of the well. Although considered to have a very low overall permeability, this test has demonstrated that certain zones encountered in the well may be capable of sustained production of high temperature fluids.

When the hole was "dried" to a depth of about 2300 m, fluids in the No-Good Zone had sufficient

pressure to purge any remaining materials which had invaded the Zone. The high pressure discharge at surface was probably a true expression of the potential of the No-Good Zone. However, cooler water (about 160°C) flowing downward outside the slotted liner encountered the hot rising fluids and quenched the flow, thereby effectively reducing any possibility of it rising further to surface.

Calculations based on the observed wellhead pressure of 800 kPa indicate an electric generation potential for the third well to be on the order of up to 8 MW. Although no further evaluation of the No-Good Zone is anticipated at present, it does present an attractive target and appears well worthy of future consideration. Various production options might include reconfiguring the liner/casing setup or a downhole pump. In either case, it is essential that the upper, cooler geothermal fluid be isolated from that produced by the No-Good Zone in order to maximize production potential.

#### 4.4 20kW Demonstration Turbine Tests

##### 4.1.3 Preparation, Installation and Testing of a 20 kW Demonstration Turbine

In July, 1983, preparations were begun for the installation of a small turbine on the producing well MC-1. Arrangements were made with the Electric Power Research Institute, Inc. of Palo Alto, California (EPRI) to supply a Rotary Separator Turbine.

Whereas conventional geothermal turbines with exception of binary cycle turbines, require higher temperature dry steam (usually combining the flow from several wells), the RST is a total flow type turbine ideal for the Meager Creek application as it utilizes both the steam and water fractions of the discharge from a smaller, cooler flow. Unfortunately, EPRI became involved in a legal dispute with the RST supplier and the equipment could not be supplied.

However, EPRI were able to provide a small, axial flow demonstration plant developed by Barber-Nichols Engineering of Denver, Colorado. This single flash steam turbine was installed and tested under varied conditions during spring and summer, 1984. The test program was completed in October, 1984, however, before it could be demobilized, flooding stranded the equipment on site. The separator, turbine and generator were winterized and remained at Meager Creek until May, 1985.

### Turbine Installation

On-site preparations for the steam turbine began in late 1983, with the delivery of the generator, separator, and turbine to Meager Creek in mid-November. Installation proceeded slowly because of logistic difficulties imposed by the approaching winter season.

Much of the first three months of installation was consumed by the reconditioning of the separator unit. The equipment supplied had been previously used and arrived at the site in only fair condition. Installation was completed by April, 1984 and the testing program began shortly thereafter (Figure 5a).

### Turbine Testing

In order to provide EPRI with a reasonable working assessment of the steam turbine, a variety of tests were designed in a program which was conducted during summer, 1984. Twenty-four tests ranging in length from one to six hours were run, with observations of temperature, pressure, flow rate and power output being made at a number of points in the separator-turbine test loop (designated, for example, T1, P1, F6a, W8 in Figure 5b). Data from "Power System Tests" are included (Appendix) as sample observations. The power was spilled to a

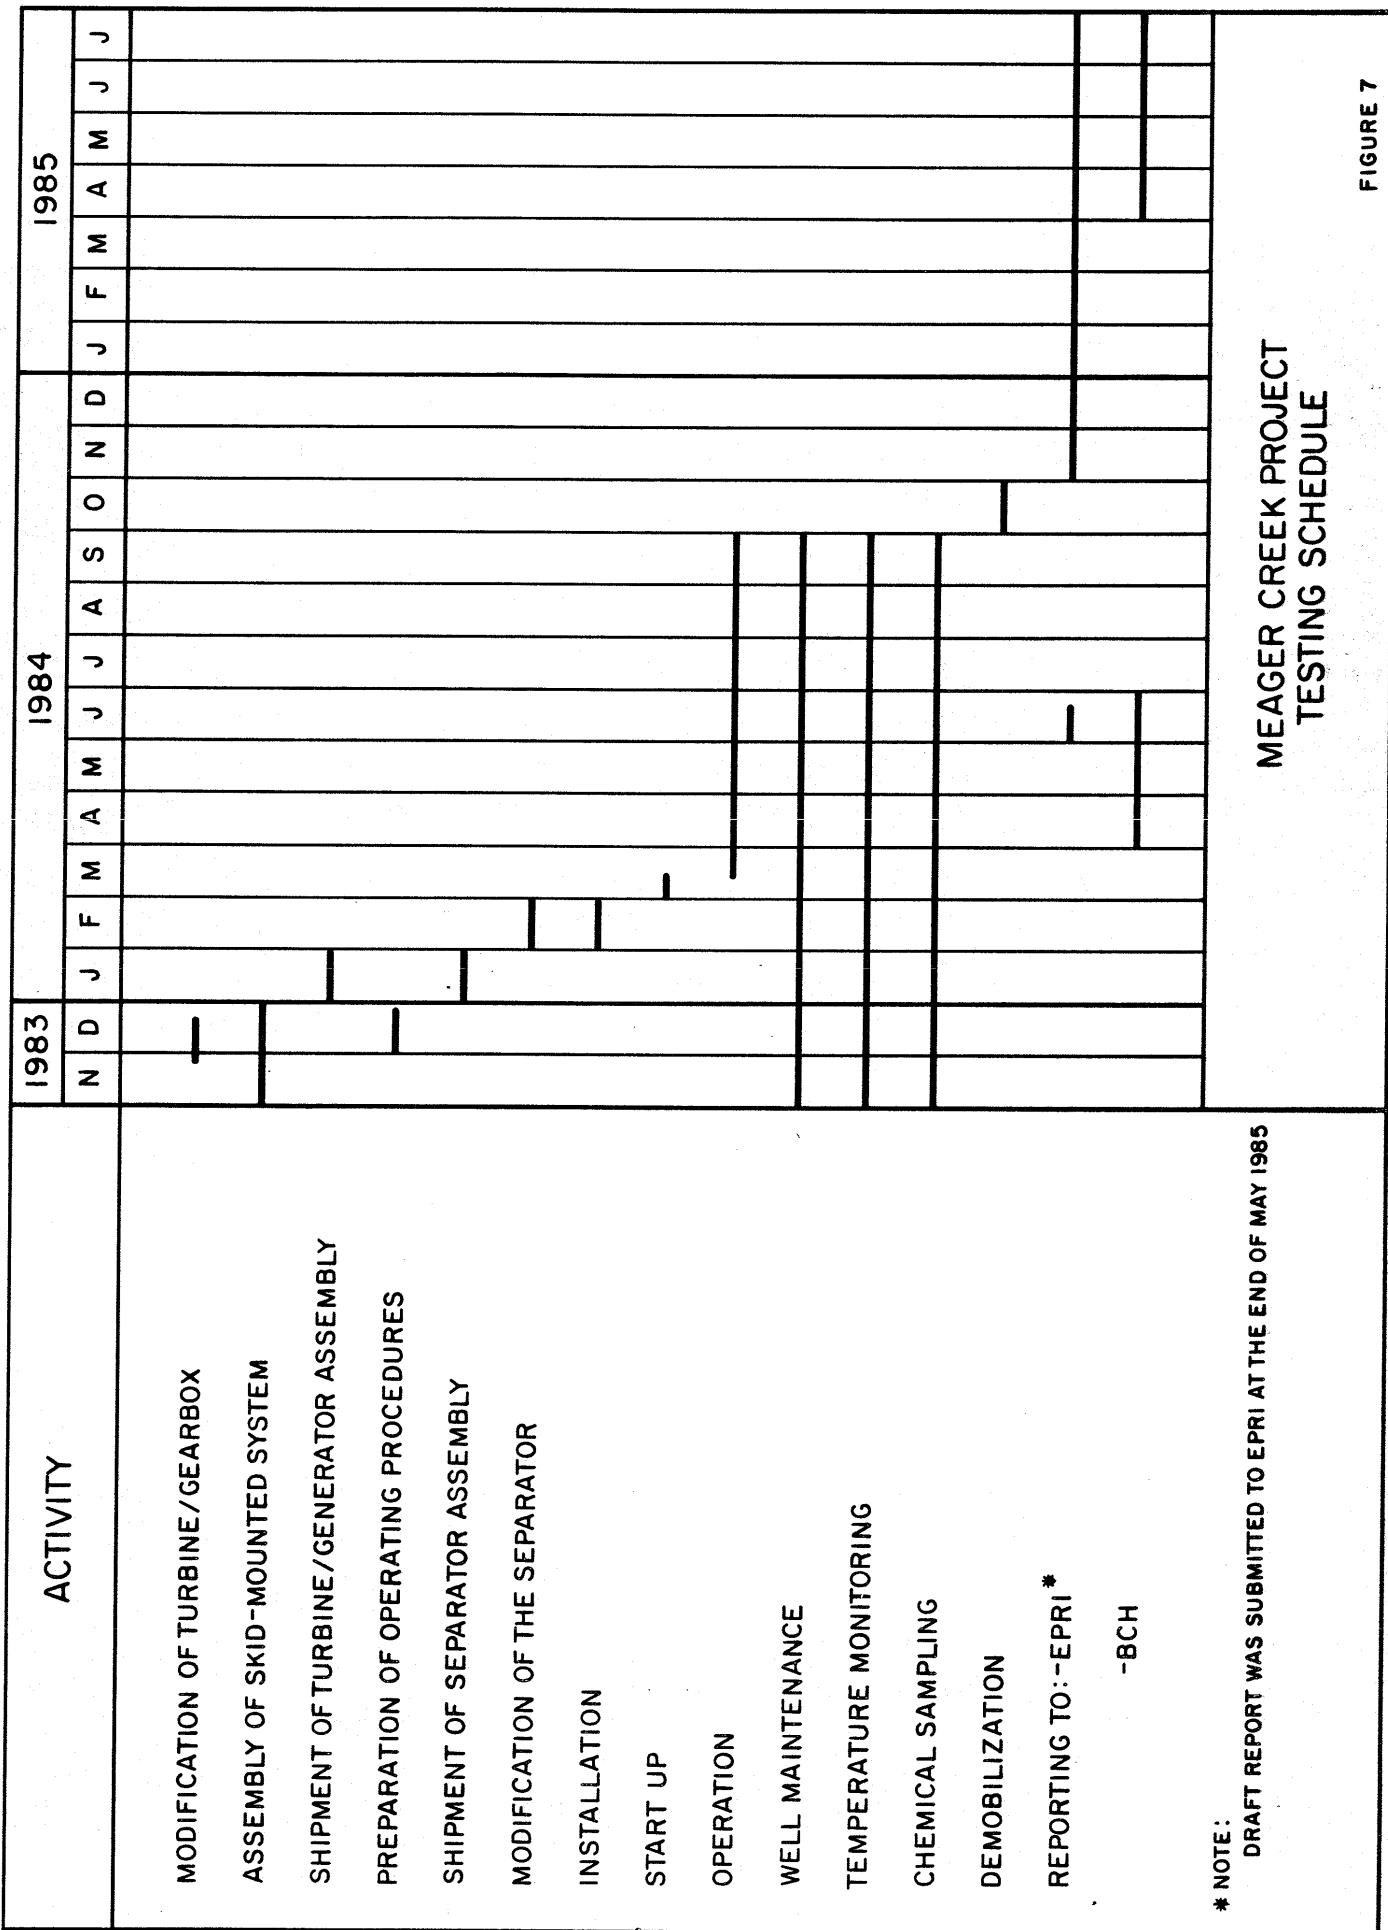

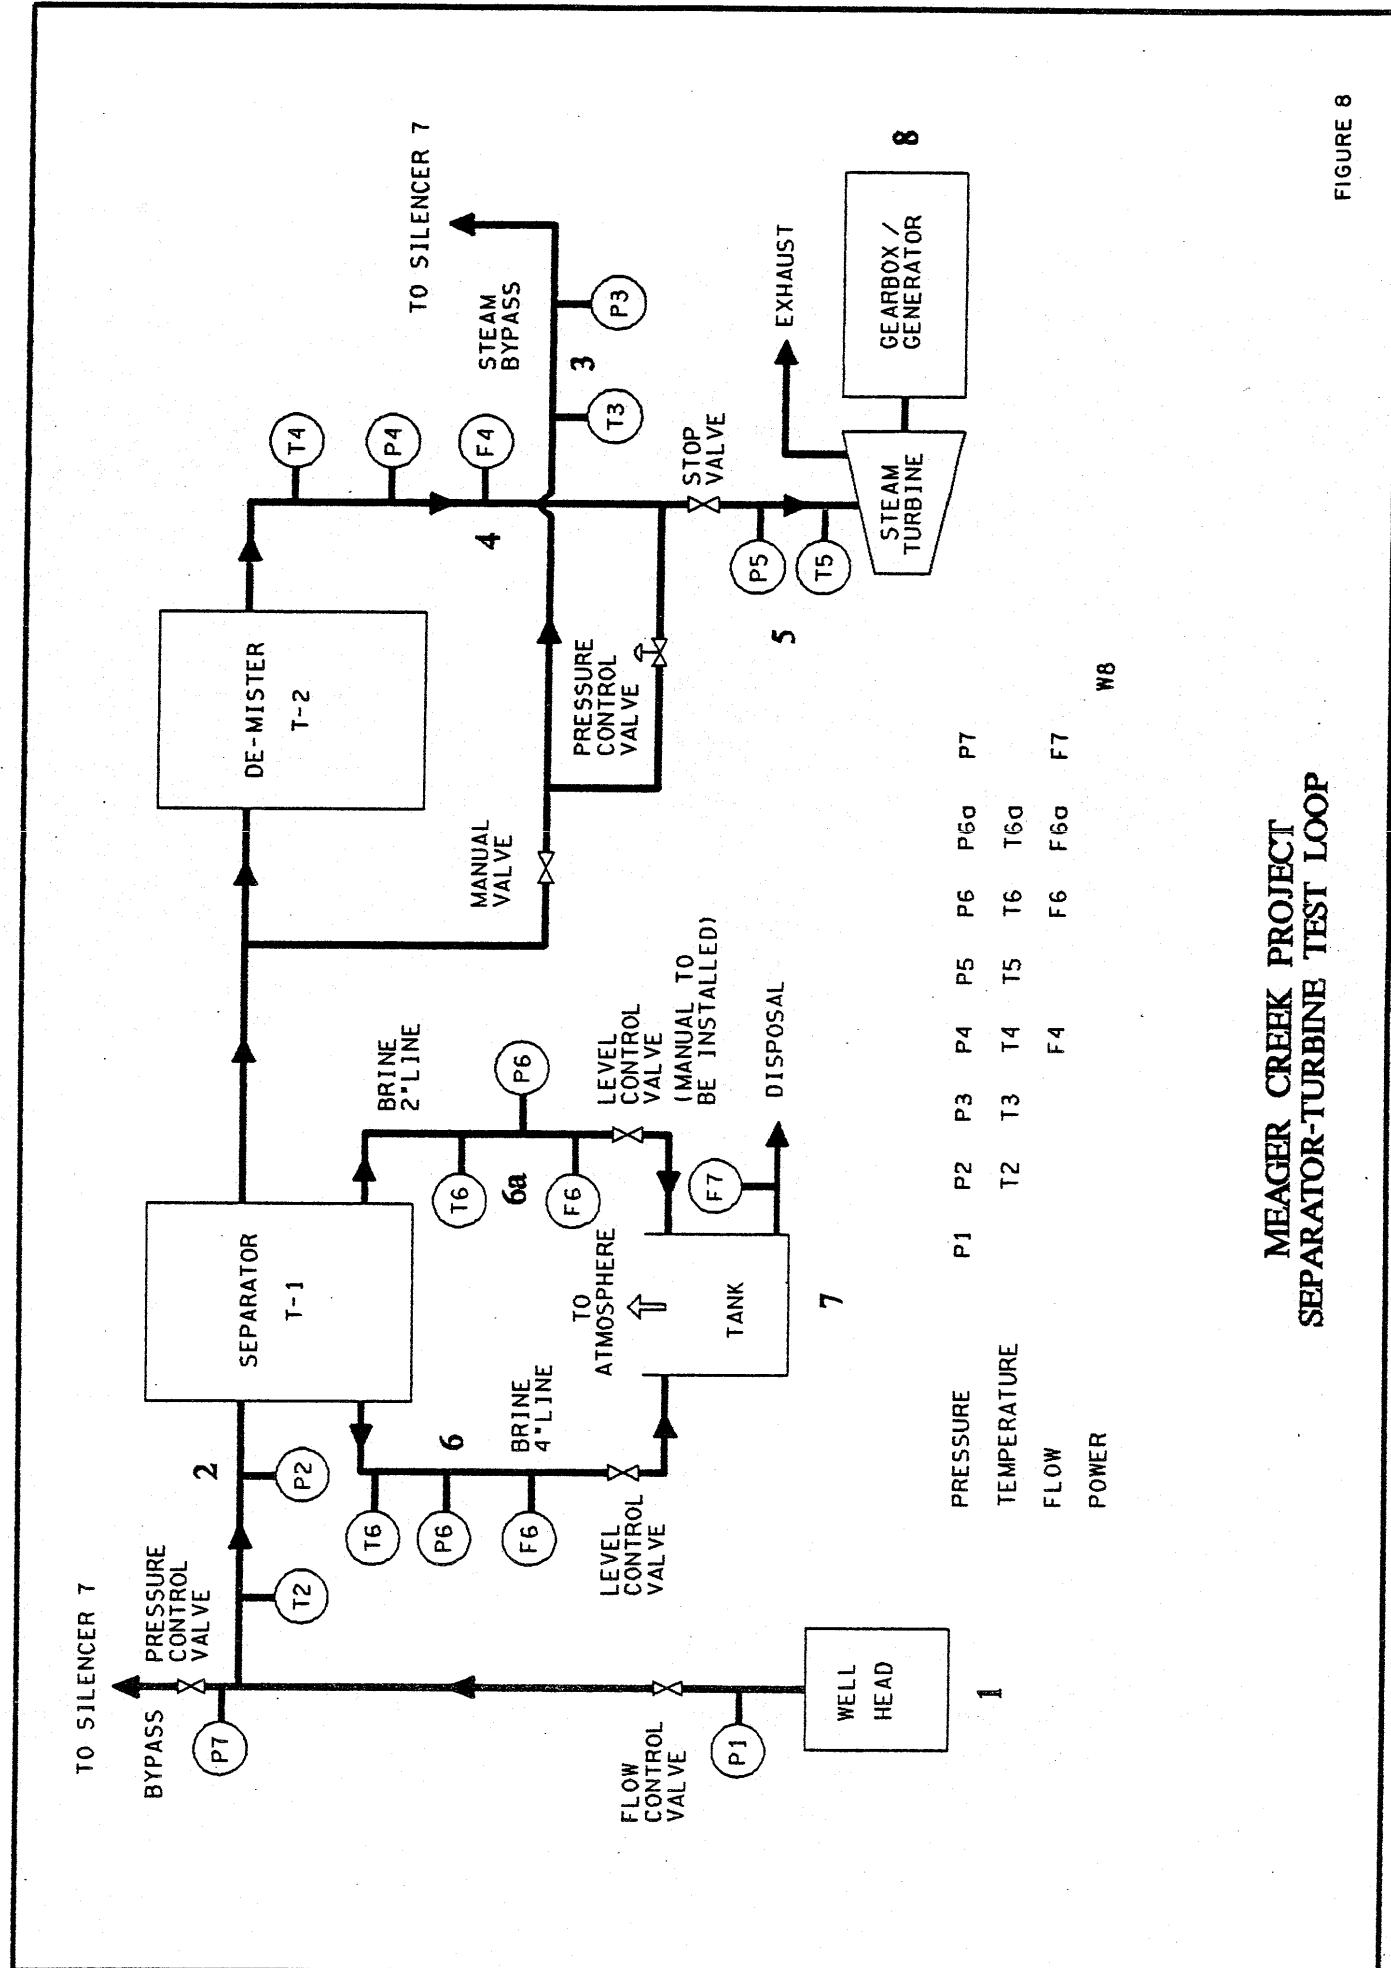

FIGURE 7

MEAGER CREEK PROJECT  
SEPARATOR-TURBINE TEST LOOP

FIGURE 8

load bank.

Although the steam turbine is rated at 20 kWe, the average output of the power tests was approximately 9-30 kWe. In order to achieve a higher electrical output, a larger input line would be required and additional nozzles installed. As set up, the 100 mm (4") input line applied a large enough back pressure at the wellhead to choke the fluid flow from the bore. A bypass line leading directly to the silencer was installed in order to maintain wellhead pressures below a critical upper limit of approximately 350 kPa.

A report to EPRI on the results of the test is under separate cover.

## 5. DISCUSSION

In furthering the development of a conceptual model for the Meager Creek geothermal system, the work conducted under the maintenance and testing program during 1983 to 1985 has been most informative. The collection of new data and the re-interpretation of existing data have significantly advanced the understanding of the reservoir characteristics.

Naturally, most of the work was concentrated on well MC-1 because of its capabilities as a

geothermal producing well. The well was targeted to intercept a hypothesized permeable volcanic breccia at a depth of 3000 to 3500 m. However, drilling complications stalled MC-1 short of this goal. Although the rock was characterized by low overall permeability, a number of shear zones and dykes associated with the Meager Creek Fault were encountered. The steeply northward dipping normal fault zone is considered to be associated with Meager Volcanic Complex eruptive activity and is a likely conduit for the movement of ascending geothermal fluids.

When first tested in 1981, MC-1 showed little potential, with comparatively low temperatures and permeabilities for a geothermal well. However, with flow testing and stimulation attempts, the well began to discharge a steam and water mixture under considerable pressure at the wellhead. Temperature surveys indicated that most of the fluid was entering the bore from the intersection with the Meager Creek Fault Zone at a depth of 1600 to 1800 m.

Continued production testing through October, 1984 appeared to have significantly improved the flow characteristics of MC-1. Recent surveys indicate that fluid temperatures continue to increase, and it may be inferred from pressure records that "production zone" permeability has increased since

testing began. Although only a proper injection/pressure fall-off test could confirm it, production has probably cleaned up the fault zone and enhanced the permeability substantially.

Although MC-1 cannot be considered a viable geothermal production well, it indicates that potential exists for exploitation of a geothermal resource from the Meager Creek Fault structure. The installation and testing of a steam turbine on the well has demonstrated the need for a better understanding of fluid flow characteristics in the Zone and the difficulties in obtaining economic fluid temperatures and pressures.

Testing has also shown that geothermal fluids in the Meager Creek system are heavily saturated with calcium carbonate and that scale control must be considered seriously in any future installation design. The corrosivity of the fluid is comparatively low by geothermal standards and the toxic element content is within workable limits. Furthermore, geochemical analyses indicate that a hotter reservoir may well be present nearby.

Work on the other two deep exploratory wells, MC-2 and -3, has been minimal throughout the maintenance and testing program. However, collection of temperature data from both wells and a flow

stimulation program on MC-3 have helped to clarify several geological and engineering aspects of the Meager Creek geothermal system.

Well MC-2 continues to heat up, showing an increase of 2 to 3°C per year. The cause of this rise is uncertain although it may be attributed to an influx of warmer fluids from the Meager Creek Fault, intercepted at 2000 m in MC-2.

Although it encountered higher temperatures and higher overall permeability than MC-1, MC-2 was incapable of sustained production during testing. This is probably accountable to the depth at which it intercepted the Meager Creek Fault. Fluid temperatures at the intersection are higher than in MC-1, however, because of an additional 300 to 400 m of cooler water in the hydrostatic column opposing production from the fault zone, hot geothermal fluids do not enter the MC-2 bore. Unusual fluctuations in the standing water level of MC-2 also indicate that cool, near surface groundwater may be entering the bore through a hole in the casing. This would help suppress the tendency for rising thermal waters to flash spontaneously.

MC-2 will may not prove to be a successful production or reinjection well if development were to proceed at Meager Creek. However, through the

testing program, it has become increasingly apparent that MC-2 represents a valuable source of data on the geothermal reservoir status.

Perhaps the most significant findings of the maintenance and testing program involved well MC-3. The 3500 m well was drilled westward, intercepting the "No-Good Zone", a near vertical fault structure running perpendicular to the Meager Creek Fault, at a depth of 3025 m. Several geochemical and geophysical surveys conducted in the vicinity had indicated that the No-Good Creek area showed considerable geothermal activity. During drilling, the structure proved sufficiently permeable to cause a total loss of circulation fluid. Although circulation was eventually regained, the permeability of the zone was severely damaged in the process. Subsequent testing determined that, despite economic temperatures at depth, the overall permeability of MC-3 was too low to consider the well a viable geothermal producer.

Attempts to stimulate MC-3 into test production met with limited success. The well bore had also penetrated the Meager Creek Fault, and can produce warm ( $160^{\circ}\text{C}$ ) water from a depth of approximately 1700 m. However, attempts to produce from the prime target at 3025 m have not been successful until November, 1983.

The airlift conducted at that time was prompted by a slow, long term heating of the well and indications of improved fluid movement at the "No-Good Zone". Hypothetically, the permeability of the fault zone would improve through the thermal degradation of the materials originally used to clog the zone in order to recover circulation.

Although flow could not be sustained, the airlift demonstrated the potential of the "No-Good Zone" as a second geothermal production target in the Meager Creek system. Apart from periodic temperature monitoring, economic considerations have stalled further investigation of the Zone. However, future studies would be well advised to focus exploration efforts on the "No-Good" structure.

## **Appendix A**

### **Temperature Run Data 1983/84-1984/85**

#### **Temperature Run Data**

The following is a complete listing of temperature data for surveys conducted on the three deep exploratory wells during 1983-84.

Well: MC-1 Survey Date: 3/09/83  
Survey number: KT-32 Element number: 148

Remarks: Discharging following mechanical cleaning run in early SEPT

Measured Depth (m CHF)	Vertical Depth (m CHF)	Measured Temperature (deg C)

## Appendix B

### E P R I Chemistry Data

#### E P R I Chemistry Data

The Electric Power Research Institute, in cooperation with B.C. Hydro, sent its mobile geothermal chemistry lab to Meager Creek in late July, 1983 in preparation for the installation of a small, demonstration steam turbine later that year. The mobile lab contains some of the most advance sampling equipment available, and its crew is specially trained in the collection and analysis of fluid samples from geothermal sites. The following is a draft report submitted to EPRI by the Rockwell International scientists who performed the sampling and analysis of the geothermal fluids from well MC-1.

DATE: August 1983

Prepared by: Rockwell International  
as a result of field operations of  
EPRI's Mobile Geothermal Chemistry  
Lab., RP741-1

**Special Test, Well MCG-1      Brine, Stream and Solids**

Samples were collected on 29 July 1983; the well was flowing under stable conditions at approximately thirty percent of full flow. A sampling port (A) was available and used for collection of brine samples. The fluid sampling system was attached at port A, but no noncondensable gas was measured, indicating that the steam fraction was going to the muffler and not to port A. Only brine samples were collected at the wellhead; these included raw, acidified, flow, and sulfide samples.

The liquid fraction from the muffler was allowed to form a stream and flow down the hillside. Four raw samples were collected from the stream.

2015 ~ 20 yards from well  
2016 ~ 75 yards from well  
2017 just before the road  
2018 pond near well.

Two solid samples were collected: 2019 weir box  
2020 stream.

The diagram on the next page demonstrates the location of the sampling sites and flow streams.

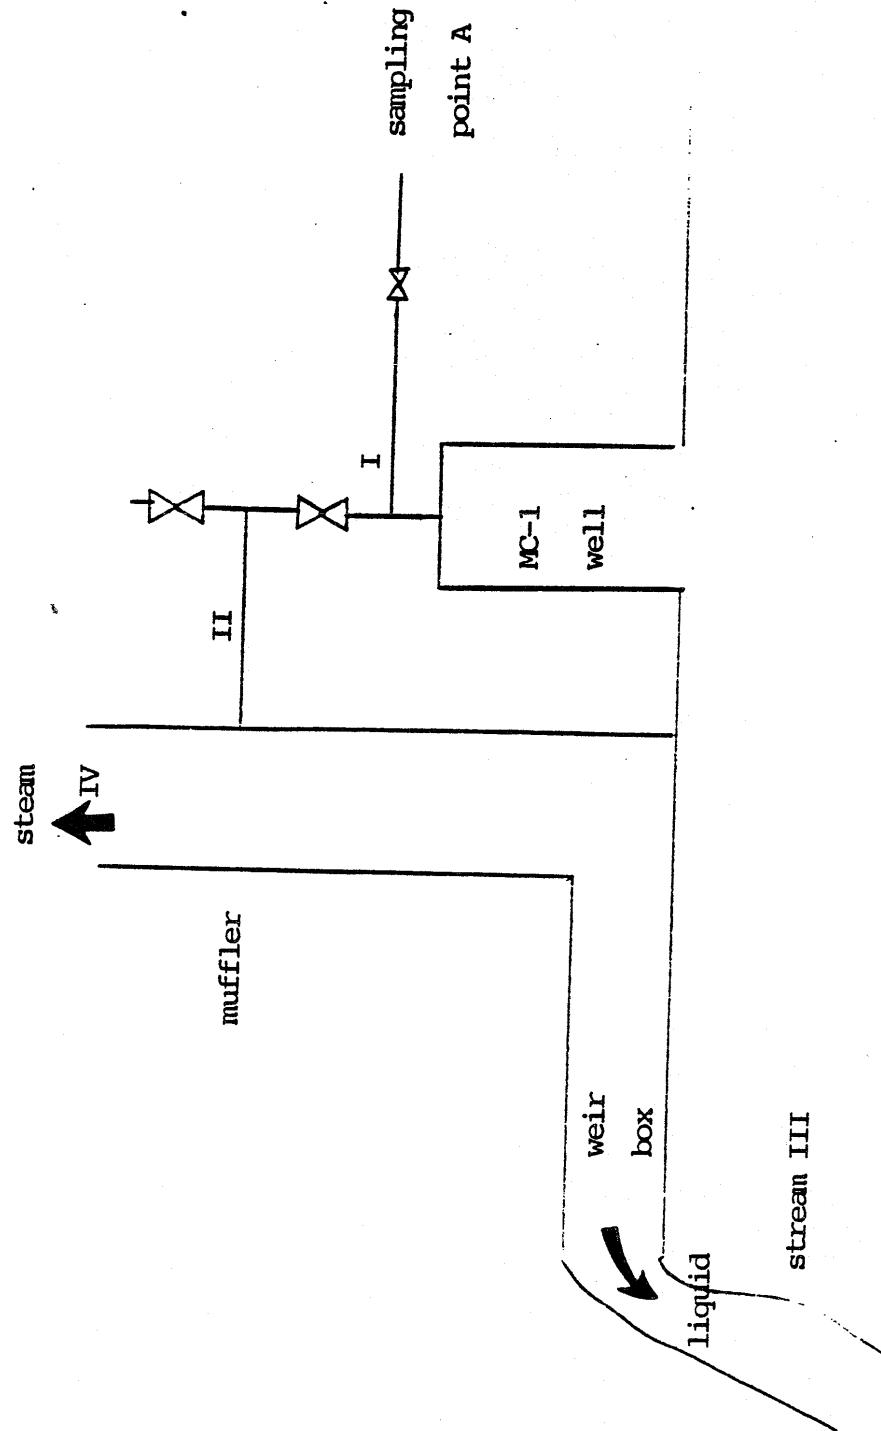

All values reported represent the samples as collected, prior to stabilization, dilution or analysis.

CHEMICAL ANALYSIS REPORT - CHEMLAB

Key to Symbols

<u>Units</u>		<u>Sample Type</u>
mg/kg = milligrams/kg		H <sub>2</sub> S -- Trapped in zinc acetate with ΔT sampling. Collected in polyethylene bottle.
ppm = parts/million		CO <sub>2</sub> -- Trapped in NaOH with ΔT sampling. Collected in polyethylene bottle.
(M/M) = mass ratio		SI -- Diluted without pre-cooling 1 part sample to 9 parts distilled water ice. Collected in polyethylene bottle.
mv = millivolts		R -- Raw sample with ΔT sampling collected in acid washed and thoroughly rinsed polyethylene bottle.
NTU = National Turbidity Units		A -- Acidified. 10 ml conc. HNO <sub>3</sub> + 990 ml sample with ΔT sampling. Collected in acid washed polyethylene bottle.
μmho/cm = micromho/centimeter		G -- Gas sample. Collected by ΔP sampling in teflon-lined stainless steel bomb unless otherwise noted.
N.D. = Not detected		C -- Condensate sample. Taken by ΔP sampling from boiling water condenser separator.
L = liter		F -- Flow through sampling probe. Sample analyzed at time of sampling.
T = temperature		FSS -- Fluid sampling system was used to collect T, P, and flow data in calculations
P = pressure		S -- Deposited Scale
AA = atomic absorption		Sample Modes
API = American Petroleum Institute		ΔT -- Temperature drop
V = volume		ΔP -- Pressure drop
kg = kilogram		Scale -- Scrapings
g/ml = grams/milliliter		
ZnAC = zinc acetate

## CHEMICAL ANALYSIS REPORT

CHEMLAB

KIND OF TEST: special, solidsSAMPLE NUMBER: 2019LOCATION: weir box

DATE	METHOD	MAJOR CONSTITUENTS
9-9	XRD	<u>CaCO<sub>3</sub></u>
	XRF	<u>Ca</u>

	MINOR CONSTITUENTS
	<u>Fe<sub>3</sub>O<sub>4</sub></u>
	<u>Fe, Sr</u>

ELEMENTS: CaCO<sub>3</sub> - aragonite and calcite presentFe<sub>3</sub>O<sub>4</sub> - magnetiteXRF scans elements Al - U only (Na, Mg, O not accessible)

## CHEMICAL ANALYSIS REPORT

CHEMLAB

## KIND OF TEST: special, solids

**SAMPLE NUMBER:** 2020

**LOCATION:** stream

DATE \_\_\_\_\_ METHOD \_\_\_\_\_ MAJOR CONSTITUENTS

XRI — 9-9

MINOR CONSTITUENTS

四

**COMMENTS:**

XRD showed no crystalline phases present; solid appears to be an amorphous silicate

XRF scans elements Al - U only (Na, Mg, O not accessible)

## Appendix C

### Well Chemistry Data

(as analysed by B.C. Hydro - Surrey Research Lab)

#### Well Chemistry Data

Water samples from well MC-1 are routinely collected and shipped to the B.C. Hydro Surrey Research and Development Lab for analysis. The following is a summary of the well chemistry data over the past two years. Also included are analyses of samples from wells MC-2 and MC-3 collected during flow tests in late 1982.

## TEAGER GEOCHEMICAL ANALYSIS RESULTS

## PROJECT

## Appendix D

### List and Content of Computer Data Diskettes

Majority of field data is stored on the floppy diskettes using IBM PC computer. The diskettes also include a variety of programs designed as an evaluation tool.

NOTE: Diskette P - Pressure Data  
T - Temperature Data  
C - Chemistry Data  
S - Slimhole Exploration Data  
IN - Invoice and Accounting Data  
F - Various Programs  
D - Various Database Programs  
G - Various Geochemical Programs  
ST - Analytical Programs  
PST - Turbine Testing Data  
TXT - Reporting Text etc.

DISKETTE - P1
