MOUNT POLLEY MINING CORPORATION
MOUNT POLLEY MINE

STAGE 5 DESIGN OF THE TAILINGS STORAGE FACILITY
(REF. NO. VA101-01/12-1)

EXECUTIVE SUMMARY

The Mount Polley gold and copper mine is owned by Mount Polley Mining Corporation (MPMC). It is located 56 kilometres northeast of Williams Lake, in central British Columbia. Mount Polley mine re-opened in the March 2005 after managing the facilities for Care and Maintenance activities since October 2001. MPMC is currently mining the Bell and Wight Pits with the tailings material being deposited as slurry into the Tailings Storage Facility (TSF). Process water is collected and recycled back to the mill for recycle in the milling process.

This report provides supporting documentation to allow for MPMC to permit the staged expansion of the TSF embankments from the existing permitted elevation of 948 m for the Stage 4 expansion to a new Stage 5 elevation of 951 m. The Stage 5 design of the TSF is consistent with the general design and construction methodology of the TSF to its ultimate elevation of 965 m and consists of adding 3 m to the current crest elevation of the embankments using the modified centreline construction method. This elevation will provide sufficient storage in the TSF for approximately one year of operations while maintaining the required water storage and freeboard requirements. Details on the ultimate design of the TSF were issued to the Ministry of Energy and Mines (MEM) in March 2005 (Knight Piésold Report “Design of the Tailings Storage Facility to Ultimate Elevation”, Ref. No. VA101-1/8-1). MPMC requested at that time that MEM consider permitting the TSF to its ultimate elevation of 965 m, assuming that there would be no significant changes in the design or construction methodology of the TSF. Significant changes in the design or construction methodology of the TSF would require MPMC to submit the revised design for permit approval prior to expanding the TSF embankments. Detailed design reports, construction drawings, technical specifications, and construction reports would be prepared for each stage of the TSF expansions by a suitably qualified Professional Engineer.

A total of 56 vibrating wire piezometers have been installed in the tailings, foundation, embankment fill materials and drains to date. Additional vibrating wire piezometers will be installed during the Stage 5 expansion of the TSF. The inclinometers installed downstream of the Main Embankment through the lacustrine unit will be extended though the shell zone as it is constructed. Survey monuments will be installed on the completed Stage 5 crest.

Embankment drainage provisions have been incorporated into the design of the TSF to facilitate drainage of the tailings mass, dewater the foundation soils, and to control the phreatic surface within the embankments. The components of the drainage systems consist of foundation drains, chimney drains, longitudinal drains, outlet drains, and upstream toe drains. The upstream toe drains are effective in lowering the phreatic surface, which increases embankment stability and
seepage control. The upstream toe drains also remove a certain amount of filtered water from the impoundment, and it may be possible to establish water discharge points below the seepage collection ponds if water quality objectives are met. An upstream toe drain already exists at the Main Embankment and one will be installed at the Perimeter Embankments during Stage 5. An upstream toe drain will be installed at the South Embankment during a future staged expansion.

Foundation drains, along with a sump and seepage recycle pumpback system will be installed at the South Embankment prior to placement of the downstream shell zone material.

The TSF is required to have sufficient live storage capacity for containment of runoff from the 24-hour PMP volume of 679,000 m$^3$ at all times, which would result in an incremental rise in the tailings pond level of approximately 0.39 m. The 24-hour PMP allowance is in addition to regular inflows from other precipitation runoff, including the spring freshet. The TSF design also incorporates an additional allowance of 1 meter of freeboard for wave run-up.

Stability analyses were completed for static and seismic conditions and indicate that the TSF embankments are stable under static and seismic conditions and that deformations initiated by earthquake loading will be insignificant.

Knight Piésold will provide the construction drawings, technical specifications, and QA/QC for Stage 5 expansion of the TSF. Knight Piésold will also issue a construction report following the Stage 5 construction program. A Dam Safety Review is scheduled for the summer of 2006.

APPENDICES

APPENDIX A  Technical Paper on "Modified Centreline Construction of Tailings Embankments"
SECTION 1.0 - INTRODUCTION

1.1 PROJECT DESCRIPTION

The Mount Polley gold and copper mine is owned by Mount Polley Mining Corporation (MPMC). It is located 56 kilometres northeast of Williams Lake, in central British Columbia. The project site is accessible by paved road from Williams Lake to Morehead Lake and then by gravel road for the final 12 km. The location of Mount Polley Mine is shown on Figure 1.1. Mount Polley Mine started production in 1997 and had milled approximately 27.5 million tonnes of ore prior to temporarily suspending operations from October 2001 to March 2005. MPMC is currently mining the Bell and Wight Pits with the tailings material being deposited as slurry into the Tailings Storage Facility (TSF). Process water is collected and recycled back to the mill for recycle in the milling process. The average throughput for 2005 was approximately 15,000 tpd. Aerial photographs of Mount Polley Mine obtained in October 2005 are shown on Figures 1.2 and 1.3. The overall Mount Polley Mine site plan is shown on Drawing 100. The general arrangement of the TSF is shown on Drawing 102.

1.2 SCOPE OF REPORT

The Tailings Storage Facility at Mount Polley Mine has an ultimate elevation of 965 m. This elevation will provide sufficient storage in the TSF for approximately 85 million tonnes of tailings while maintaining the required water storage and freeboard requirements. Details of the design of the TSF to an ultimate elevation of 965 m were issued in the Knight Piésold Report "Design of the Tailings Storage Facility to Ultimate Elevation", Ref. No. VA101-1/8-1, March 14, 2005.

MPMC is currently in the process of raising the TSF embankments to the currently permitted elevation of 948 m. Knight Piésold provided the design, technical specifications, and QA/QC for the Stage 4 expansion of the TSF. The scope of this report is to provide supporting documentation to allow for MPMC to obtain permits for the Stage 5 expansion of the TSF embankments to an elevation of 951 m. This elevation will provide sufficient storage in the TSF for approximately one year of operations while maintaining the required water storage and freeboard requirements. The Stage 5 design of the TSF is consistent with the design and construction methodology of the TSF to its ultimate elevation of 965 m, and consists of adding 3 m to the current crest elevation of the embankments using the modified centreline construction method. The drawings contained within this report are for permitting support and will be updated prior to being “Issued for Construction”.

1.3 REFERENCES

This report references the following documents, which provide key supplementary information:

SECTION 2.0 - TAILINGS STORAGE FACILITY

2.1 GENERAL

The principal objectives of the TSF are to provide secure containment for tailings solids and to ensure that the regional groundwater and surface water flows are not adversely affected during or after mining operations. The design and operation of the TSF is integrated with the overall water management objectives for the entire mine development, in that surface runoff from disturbed catchment areas is controlled, collected and contained on site. An additional requirement for the TSF is to allow effective reclamation of the tailings impoundment and associated disturbed areas at closure to meet land use objectives.

The main components of the TSF are as follows:

- The TSF embankments incorporate the following zones and materials:
  - Zone S - Core zone - fine grained glacial till.
  - Zone CS - Upstream shell - cycloned or spigotted tailings sand.
  - Zone B - Embankment shell zones - fine grained glacial till.
  - Zone F - Filter, drainage zones, and chimney drain - processed sand and gravel.
  - Zone T - Transition filter zone - select well-graded fine-grained rockfill.
  - Zone C - Downstream shell zone – rockfill.
  - Zone U – Upstream shell zone – parameters vary depending on material availability.

- A low permeability basin liner (natural and constructed) covers the base of the entire facility, at a nominal depth of at least 2 m. The low permeability basin liner has proven to be effective in minimizing seepage from the TSF as there have been no indications of adverse water quality reporting to the groundwater monitoring wells.

- A foundation drain and pressure relief well system, located downstream of the Stage 1B Main Embankment. The foundation drain and pressure relief well system prevent the build-up of excess pore pressure in the foundation, and transfer groundwater and/or seepage to the collection ponds.

- Seepage collection ponds located downstream of the Main and Perimeter Embankments. These ponds were excavated in low permeability soils and store water collected from the embankment drains and from local runoff.

- Instrumentation in the tailings, earthfill embankments and embankment foundations. This includes vibrating wire piezometers, survey monuments, and slope inclinometers.

- A system of groundwater quality monitoring wells installed around the TSF.

The tailings embankments have been designed for staged expansion using the modified centreline construction method. A technical paper on the “Modified Centreline Construction of Tailings Embankments” is included in Appendix A.
2.2 HAZARD CLASSIFICATION

The classification of the TSF has been assessed using the Canadian Dam Association and the British Columbia Dam Safety Regulation guidelines. These guidelines look at the consequences of failure and consider life safety, economic and social losses, and environmental and cultural losses. The life safety category considers the potential for multiple loss of life after ascertaining the degree of development within the inundation area. The economic and social loss category considers damage to infrastructure, public and commercial facilities that are in and beyond the inundation area. This includes damage to railways, highways, powerlines, residences etc. The environmental and cultural loss considers damage to fish habitat at the regional, provincial, and national level, wildlife habitat, including water quality, and unique landscapes or sites of cultural significance.

The assessment indicates that the TSF has a “HIGH” hazard classification (or consequence category) based on the economic and social loss category. The classification for the life safety and environmental and cultural loss categories is “LOW”, as there is low potential for multiple loss of life, the inundation area is typically undeveloped, and there is unlikely to be loss or significant deterioration of provincially or nationally important fish habitat. However, the ultimate TSF embankments will be up to 55 m high, and the estimated costs associated with repairing the damage, loss of service to the mine, and the potential economic impact on Imperial Metals, could exceed $1,000,000, which places the TSF into the “HIGH” economic and social losses category under the British Columbia Dam Safety Regulation guidelines.

The classification of dams under the Canadian Dam Association and the British Columbia Dam Safety Regulation guidelines corresponds to consequences of failure and does not relate in any way to the likelihood of failure. The embankment has been designed to accommodate a maximum design earthquake (MDE) corresponding to 50% of the maximum credible earthquake (MCE) and the impoundment is sized to contain the probable maximum precipitation (PMP) storm event. The TSF at Mount Polley Mine is visually inspected daily by MPMS staff during operations, and the embankment instrumentation is monitored at regular intervals during operations with the frequency of monitoring increasing during the TSF expansion phases. The likelihood of dam failure is therefore extremely low.

2.3 FOUNDATION CONDITIONS

The tailings basin is generally blanketed by naturally occurring well-graded low permeability glacial till, which functions as an in-situ soil liner. However, a basin liner was constructed just upstream of the Main Embankment during Stage 1a to ensure that the basin liner had a minimum thickness of 2 m throughout the tailings basin. The constructed basin liner was tied into the Main Embankment core zone and the existing basin liner where the in-situ thickness exceeded 2 m.

The south ridge between the Main and South Embankments was investigated during the Stage 4 construction program to confirm the thickness of the basin liner in this area. The investigation found that the basin liner thickness was less than the required minimum thickness of 2 m near the crest of the ridge. A basin liner was constructed in this area during the Stage 4 construction
program to ensure that the basin liner had a minimum thickness of 2 m throughout this area and that it tied into the South Embankment core zone.

The foundation conditions at the Main Embankment consist of low permeability glacial till material at surface underlain by fluvial and lacustrine silts up to 20 m thick. The foundation conditions at the Perimeter Embankment consist of low permeability glacial till throughout that is generally in excess of 5 m thick. The foundation conditions at the South Embankment consist of a relatively thin, low permeability glacial till material overlying bedrock. Details of the site geological investigations can be found in the Knight Piésold Report "Updated Design Report", Ref. No. 1627/2, June 6, 1997.

Laboratory testwork on the foundation soils indicates that the materials have adequate shear strength to ensure foundation stability of the embankments. Artesian pressures exist at the base of the Main Embankment. Pressure relief wells have been installed previously at this location to depressurize the underlying glaciofluvial deposits. Ongoing monitoring has confirmed that design objectives are being met during on-going operations.

2.4 TAILINGS AND RECLAIM PIPELINES

The tailings pipeline comprises 7 km of HDPE pipe of varying diameters and pressure ratings and has a design flow of 20,000 tonnes/day at 35% solids by dry weight. The tailings pipeline has a single, movable discharge section, which allows for controlled deposition of tailings from an isolated section of the embankment to evenly distribute tailings from around the perimeter of the facility. Evenly discharging the tailings from around the facility optimizes the development of tailings beaches and keeps the supernatant pond clear of the embankments, thereby increasing seepage paths and limiting seepage loss from the facility. Beached tailings, when left to drain and consolidate, form the competent foundations needed for the modified centreline construction embankment raises. The optimized tailings beach development from Stages 5 through 10 is shown schematically on Figure 2.1. Tailings material was also being used during the Stage 4 construction program as Zone U material, which is located upstream of the core zone on the tailings beaches.

The reclaim pipeline system returns water from the TSF to the mill site for re-use in the process. The system comprises a pump barge, a reclaim pipeline and a reclaim booster pump station.

The tailings pipeline, reclaim system and tailings deposition within the TSF are reviewed annually as part of the annual inspection and as part of each design phase for the expansion of the TSF.

2.5 EMBANKMENT DRAINAGE PROVISIONS

Embarkment drainage provisions have been incorporated into the design of the TSF to facilitate drainage of the tailings mass, dewater the foundation soils, and to control the phreatic surface within the embankments. The components of the drainage systems consist of foundation drains, chimney drains, longitudinal drains, outlet drains, and upstream toe drains. The conveyance pipework for all of the drains terminates in the drain monitoring sumps at the Main and Perimeter
Embankments where the drain flows and water quality are monitored. A drain monitoring sump will be installed at the South Embankment during the Stage 5 construction program. The drainage systems are reviewed as part of the annual inspection and as part of each design phase for the expansion of the TSF. The drainage provisions for the TSF are as follows:

**Foundation Drains** - A system of foundation drains was installed in the Main and Perimeter Embankment foundations to improve the foundation conditions and enhance the dewatering of near surface soils. Pressure relief wells and pressure relief trenches connected to the foundation drains were included to depressurize the underlying glaciofluvial deposits to enhance the stability of the embankment.

**Chimney, Longitudinal and Outlet Drains** - A Chimney drain has been included in the Main and Perimeter Embankments and is planned for the South Embankment. The chimney drains provide a contingency drainage measure for control of the phreatic surface in the embankment and will also function as a crack stopper downstream of the core zone. Water collected in the chimney drains is routed to the drain monitoring sumps via the longitudinal and outlet drains.

**Upstream Toe Drains** – An upstream toe drain has previously been installed in the Main Embankment and one is planned for installation in the Perimeter Embankment during the Stage 5 construction program. An upstream toe drain will be installed at the South Embankment during a future stage. The purpose of the upstream toe drains is to drain and consolidate the tailings mass near the embankments. The inclusion of upstream toe drains also provides seepage control within the embankment and reduces the likelihood of piping. Piezometer records at the Main Embankment indicate that the upstream toe drain is effective in draining the sandy tailings adjacent to the embankment.

The upstream toe drains also remove a certain amount of filtered water from the impoundment, and it may be possible to establish water discharge points below the seepage collection ponds if water quality objectives are met. Experience at the site has shown that the quality of water flowing from the toe drains is better than supernatant water quality for most parameters, largely because the suspended solids are effectively filtered before the water enters the drains. The installation of the upstream toe drains was recommended during an independent third party review conducted by Fred Matich of MATM in 1997 in a "Geotechnical Review, Drainage Aspects" for the Main Embankment.

The upstream toe drain at the Perimeter Embankment will exit the TSF at the west abutment in the in-situ foundation materials. The conduit through the abutment will consist of a concrete encased pipe, with the concrete encasement having sloped sides to allow for superior compaction of the earthfill materials against it. A filter diaphragm consisting of Zone F material will be constructed for seepage and piping control. The conduit will not contain seepage cut-off walls. Flows from the Perimeter Embankment upstream toe drain will flow into the sump located Perimeter Embankment Seepage Collection Pond for measurement and sampling prior to being recycled back to the TSF. Details of the upstream toe drain at the Perimeter Embankment are shown on Drawing 240.
2.6 SEEPAGE COLLECTION PONDS

The seepage collection ponds collect water from the embankment drain systems and from local runoff. The Main Embankment Seepage Collection Pond, located immediately downstream of the Main Embankment, was completed at the start of the Stage 1a construction program in 1997. The Perimeter Embankment Seepage Collection Pond was excavated during Stage 1b construction in 1997. These ponds were excavated in low permeability glacial till materials. A sump and seepage recycle pumpback system will be installed at the South Embankment during Stage 5.

2.7 INSTRUMENTATION

Piezometers

A total of 56 vibrating wire piezometers have been installed at the TSF to date. The piezometers are grouped into tailings, foundation, embankment fill and drain piezometers and have been installed along eight planes designated as Monitoring Planes A to H. An additional monitoring plane (Plane i) will be installed at the South Embankment. The piezometer locations are shown on Drawings 336, 338, 340, 346, 347, 348 and 349. The piezometers are read monthly during operations and weekly during TSF construction programs as per the OM&S Manual. The piezometer data is reviewed annually as part of the annual inspection. The piezometer records for the TSF have recently been reported in Knight Piésold Report “2005 Annual Inspection”, (Ref. No. VA101-1/11-1, May 3, 2006).

Inclinometers

Five slope inclinometers have been installed to date at the toe of the Main Embankment through the lacustrine silts to measure potential deformation of the embankment materials. Three of the inclinometers were installed during the Stage 4 construction program. The inclinometers will be carefully extended through the shell zone material as it is raised. There have been no significant deviations in the inclinometers since they were installed.

Survey Monuments

The survey monuments installed on the Stage 3B embankment crest following the 2001 construction program were removed during the Stage 3C construction program and have not been replaced as the Stage 3C construction program blended into the Stage 4 construction program. New survey monuments may be installed on the embankment crests during the Stage 4 construction program depending on its completion date, otherwise, survey monuments will be installed following the Stage 5 construction program, which is scheduled for the summer and fall of 2006.
2.8 WATER MANAGEMENT

MPMC mine personnel complete on going surface water monitoring and water management activities to ensure compliance with the current mine permits. The water balance for the TSF is updated regularly by MPMC with periodic reviews by Knight Piésold. The water balance was recently reviewed by Knight Piésold in February 2006. The site climatic conditions were reviewed by Knight Piésold in 2004 and the water balance input parameters were adjusted accordingly to better reflect site conditions. The TSF is currently operating with a water budget surplus, as total inflows from precipitation and surface runoff exceed losses from evaporation, void retention and seepage removal. The TSF is required to have sufficient live storage capacity for containment of runoff from the 24-hour PMP volume of 679,000 m$^3$ at all times, which would result in an incremental rise in the tailings pond level of approximately 0.39 m. The 24-hour PMP allowance is in addition to regular inflows from other precipitation runoff, including the spring freshet. The TSF design also incorporates an additional allowance of 1 meter of freeboard for wave run-up.
SECTION 3.0 - STAGE 5 TAILINGS STORAGE FACILITY DESIGN

3.1 GENERAL

The Stage 5 expansion of the TSF will involve raising the embankments to an elevation of 951 m. This corresponds to an increase in the crest elevation of 3 m and will provide storage for tailings and water for approximately 1 year of operations. The Stage 4 expansion of the TSF involved placing an upstream cap on the embankments to an elevation of 948 m. The Stage 5 construction of the TSF consists of expanding the embankments using the modified centreline construction method. This involves constructing the downstream shell zone (Zone C) to elevation 951 m concurrently with the Zones S, F, T and U. The design basis and operating criteria for the Stage 5 design of the TSF are shown on Table 3.1. The filling schedule and anticipated staged construction sequence of the TSF, which incorporates anticipated supernatant pond development over the next year, is shown on Figure 3.1.

Work to be completed during the Stage 5 expansion of the TSF includes the following:

- Placing the downstream shell zone material in two stages to coordinate the construction schedule with the material availability from the development of the Wight Pit. The first stage involves placing the shell zone with an interim slope of 1.4H:1V to allow the embankments to be raised using the modified centreline construction method in the timeline required to maintain the storage and free board requirements of the TSF. The shell zone will be expanded to a 2H:1V slope once the embankments have reached the Stage 5 design elevation.

- Expanding Zones S, F, T and U to elevation 951 m. The Zone S core zone will have a minimum width of 8 m. Zones F and T will be tied into the existing Zones F and T which are currently at an elevation of 944 m.

- Installing an upstream toe drain on the Perimeter Embankment to drain and consolidate the tailings mass near the embankment.

- Installing foundation drains and a sump and seepage recycle pumpback system at the South Embankment prior to placement of downstream shell zone material.

- Extending the slope inclinometers at the Main Embankment concurrently with the downstream shell zone.

- Installing additional vibrating wire piezometers at the existing monitoring planes with an additional plane being located at the South Embankment. The piezometer cables will be extended to readout boxes located beyond the ultimate toe of the embankments. The proposed locations of the new piezometers are shown on Drawings 346, 347, 348 and 349.

- Installing survey monuments on the Stage 5 crest.

The Stage 5 Main Embankment Plan, Section and Details are shown on Drawings 210, 215 and 216, respectively. The Stage 5 Perimeter Embankment Plan, Section and Details are shown on Drawings 220, 225 and 226, respectively. The Stage 5 South Embankment Plan and Sections are shown on Drawings 230 and 235, respectively. The material specifications are shown on Drawing 104. Longitudinal and foundation drain details for the South Embankment are shown on Drawing 236.
Knight Piésold will provide the construction drawings, technical specifications, and QA/QC for Stage 5 expansion of the TSF. Knight Piésold will also issue a construction report following the Stage 5 construction program.

3.2 STABILITY ANALYSIS

Stability analyses for the TSF embankments were performed using the limit equilibrium computer program SLOPE/W. Static and seismic stability analyses were conducted to investigate the stability of the Main and Perimeter Embankments during operations. Material parameters adopted for the tailings, foundation and earth embankment materials were based on testwork from the 1995 and 1997 geotechnical investigations, from the various quality control records obtained during construction of previous stages, and from experience with typical values for similar materials. The analyses were completed to model upstream and downstream stability and conservatively assumed a partially consolidated upstream tailings mass. The downstream stability analyses considered the interim 1.4H:1V shell zone slope and the 2H:1V shell zone slope.

The results of the SLOPE/W stability analyses indicate that the factor of safety for the Stage 5 TSF embankments for static conditions ranged from 1.5 to 1.9 and 1.7 to 2.0 for downstream shell zone slopes of 1.4H:1V and 2H:1V, respectively. The factor of safety for the upstream stability analyses under static conditions for the Perimeter and Main Embankments was greater than 2.0.

The seismic analyses were completed using ground accelerations of 0.037g for the OBE. The factor of safety for the Stage 5 TSF embankments for seismic conditions ranged from 1.4 to 1.7 and 1.6 to 1.8 for downstream shell zone slopes of 1.4H:1V and 2H:1V, respectively. The factors of safety for the upstream stability analyses under seismic conditions for the Perimeter and Main Embankments were greater than 2.0.

A post liquefaction analyses was also completed to provide a conservative assessment of the downstream stability of the TSF embankments assuming the tailings material liquefies and has a very low residual strength. The factors of safety for the Main and Perimeter Embankments for post liquefaction conditions ranged from 1.5 to 1.9 and 1.7 to 2.0 for shell zone slopes of 1.4H:1V and 2H:1V, respectively. The factors of safety for the upstream stability analyses under post liquefaction conditions for the Perimeter and Main Embankments were greater than 2.0.

The results of the stability analyses are summarised on Table 3.2. The results of the stability analyses indicate that the Stage 5 TSF embankments are stable under static, seismic, and post liquefaction conditions and that the embankments do not rely on the tailings mass for stability.

</table>
| Basin Liner | • In-situ low permeability glacial till, or  
• Constructed glacial till liner. Required in areas with <2 m depth of in-situ glacial till. |
| Embankment Foundation Drains | • Installed in Main and Perimeter Embankment foundations. Foundation drains to be installed at the South Embankment during the Stage 5 expansion.  
• Foundation drains discharge to the seepage collection ponds at the Main and Perimeter Embankments via drain monitoring sumps. The foundation drain at the South Embankment will discharge to a sump where the flows will be monitored and pumped back to the TSF. |
| Stripping | • Required at areas directly affected by construction (embankments, basin liners, seepage collection ponds, reclaim barge channel stockpiles, road, etc).  
• Remove organic soil to topsoil stockpiles |

</table>
| **Function** | • Storage of tailings and process water for design life  
• Provide emergency containment of runoff for 24-hour PMP storm  
• Provision for routing PMF at closure |
| **Embankment Crest Width** | 8m min for Zone S. |
| **Embankment Height:** |  
  **Current** | El. 947 m (March 2006) |
  **Stage 5** | El. 951 m |
  **Final** | El. 965 m |
| **Design Tonnage** | 7,300,000 tpy (20,000 tpd) |
| **Solids Content of Tailings Stream** | 35% (before Millsite and waste dump runoff added to tailings stream) |
| **Freeboard:** |  
  **Operations** | 24-hour PMP event (679,000 m³) plus 1.0 m wave run.  
  **Closure** | Sufficient to provide routing of PMF plus wave run-up. |
| **Storage Capacity** | 85 million tonnes (Crest Elevation of 965 m). |
| **Tailings Density:** | 1.36 t/m³ |
| **Tailings Specific Gravity** | 2.70 |
| **Emergency Spillway Flows:** |  
  **Operations** | Not required.  
  ** Closure** | Design flow for routing PMF event. |
| **Filling Rate** | Refer to Figure 2.1. |
| **Fill Material / Compaction Requirements** | Refer Drawing 101-1/12-104. |
| **Sediment Control** | Primary control provided by the TSF Embankments. Secondary control provided by the seepage collection ponds. |
| **Seepage Control** | Seepage collection ponds and pumpback well systems. |
| **Spillway Discharge Capacity** | Not required during operations. |
| **Surface Erosion Protection** | Re-vegetation with grasses on final embankment slope. |

INSTRUMENTATION AND MONITORING

6.1 General
To quantify environmental conditions and performance characteristics of the TSF to ensure compliance with design objectives.

6.2 Geotechnical Instrumentation and Monitoring

**Piezometers**
- Measure pore pressures in drains, foundations, fill materials and tailings.
- Vibrating wire piezometers.
- Installed by qualified technical personnel.
- Four instrumentation planes for Main Embankment, three for the Perimeter Embankment, and two for the South Embankment.
- 56 piezometers installed to date.

**Survey Monuments**
- Deformation and settlement monitoring of embankments.

**Inclinometers**
- Measure potential deformation of the embankment materials.
- Installed by qualified technical personnel.
- Two slope inclinometers installed at the toe of the Main Embankment. Three additional slope inclinometers installed downstream of the Main Embankment during Stage 4.

6.3 Flow Monitoring
- To provide data for on-going water balance calculations.
- Drain flows regularly monitored.
- Reclaim and seepage pump systems flow meters.
- Tailings output monitored at millsite.
- Stream flow monitoring.

6.4 Water Quality Monitoring
- To ensure environmental compliance.
- Water quality samples taken at regular intervals from sediment ponds, drains (at drain monitor sump), groundwater monitoring wells, seepage ponds and tailings pond.
- Upstream and downstream samples for impact analysis.

6.5 Hydrometeorology
- Site weather station for input to water balance calculations.
- Site monitoring of precipitation (rain and snow), evaporation, air quality monitoring (dust, etc.).

6.6 Operational Monitoring
- Quantify operation of tailings storage facility.
- Rate of tailings accumulation in terms of mass and volume.
- Tailings characteristics and water recovery.
- Supernatant pond (depth, area and volume).

TECHNICAL PAPER ON
“MODIFIED CENTRELINE CONSTRUCTION OF TAILINGS EMBANKMENTS”

(Pages A1 to A7)
Modified Centreline Construction of Tailings Embankments

J.P. Haile & K.J. Brouwer

Knight Piésold Ltd.

Abstract: A new approach to compacted fill embankments for tailings storage facilities has been developed which is seismically stable and minimizes the fill requirements, and hence costs, for embankment construction. Modified centreline construction is similar to conventional centreline construction but with the contact between the compacted fill and the tailings sloping slightly upstream. It is, however, different from upstream construction as the stability of the embankment relies on the relatively wide thickness of compacted fill at any elevation, is independent of the tailings strength and is inherently stable even with complete liquefaction of the tailings mass. The design approach significantly reduces the quantity of fill required for on-going raises compared to conventional centreline and downstream construction as on-going construction on the downstream face is not required. This also allows for reclamation of the downstream embankment face during operations. It has been successfully implemented at the Montana Tunnels Mine in Montana, where a final embankment height of over 100 metres is planned, and forms the basis for the tailings embankment design for new projects in Alaska and British Columbia, Canada. This paper describes the principal features of this construction technique, analytical procedures and case histories.

Key Words: mine tailings storage, embankment construction, waste reclamation, seismic stability

1. Introduction

The design of tailings facility embankments in seismically active areas, or for fine-grained, low strength tailings, has historically utilized conventional earth or rockfill embankments constructed as a full embankment section similar to a water retaining dam. No reliance is placed on the strength of the tailings and the embankment section is stable under all conditions of static and seismic loading. In some instances centreline construction using either the coarse fraction of the tailings or compacted fill is used to achieve the same design objectives.

Both of these approaches require a relatively large volume of fill material for the embankment section. With staged construction the volume of fill required for each incremental raise of the embankment crest gets larger as the height of the embankment increases, and requires construction on the downstream face of the embankment over the full height. This has the added disadvantage of not allowing reclamation of the downstream face to be carried out during mining operations. Staged construction of downstream and centreline embankments is shown schematically in Figure 1.

In most instances where these embankment cross-sections are required, upstream construction on the tailings mass itself would not be an appropriate alternative, either because of poor consolidation and/or drainage conditions within the tailings, potential liquefaction and low strength of the tailings. Upstream tailings embankments can only be constructed with fine grained tailings and in seismically active areas if proper measures are taken to ensure full consolidation and drainage of the tailings [1].

The modified centreline embankment, however, offers a cost effective alternative to downstream or centreline construction in areas of high seismic risk and for tailings with little or no strength. This paper describes the principal features of this construction technique, along with analytical procedures and case histories.

The modified centreline cross-section is similar to a centreline cross-section but with the contact between the embankment fill and the tailings sloping slightly upstream. It results in the minimum volume of embankment fill for an embankment that is stable under all conditions of static and seismic loading. Furthermore, ongoing construction on the downstream face is not required and reclamation can be carried out during operations. A schematic cross-section through a modified centreline embankment is shown on Figure 2.

The modified centreline embankment achieves its stability from the relatively wide thickness of compacted fill at any elevation, and is independent of the strength of the tailings. The embankment is designed to be stable even if the tailings are fully liquefied and imposing both full fluid pressure and hydrodynamic loading on the upstream contact. The upstream contact remains stable even if the tailings are fully liquefied, when they would act as a dense fluid. The analogy is that of a slurry wall, where a dense fluid such as bentonite mud can be used to support very deep excavations.

The construction technique does require some placing of fill on the tailings beach, and hence deposition of at least a portion of the tailings stream from the embankment face is required. Ideally, the beach should be at least strong enough to support the first lift of fill. This can be achieved on very soft tailings with the assistance of a geotextile separation layer. If the beach cannot support the first lift, then the tailings can be displaced using dumped rockfill.

Modified centreline tailings embankments can be designed as either water retaining structures or fully drained embankments. When designed to be water retaining, which is obviously a more severe loading condition than if fully drained, the water retaining zone, or core, should be located as far upstream as possible, in order to provide the necessary width of drained granular material downstream of the core for stability.

3. Stability and Deformation Analyses

Stability analyses of a modified centreline embankment can be considered under three separate headings:
(i) Downstream stability,
(ii) Upstream stability,
(iii) Deformation Analyses.

Downstream Stability

Downstream stability can be analyzed initially as pseudo-static loading on the modified centreline portion of embankment only, i.e. that portion of the embankment above the full section. The forces acting on this section of the embankment are shown schematically on Figure 3.
In designing a modified centreline embankment the main variables to be considered in the geometry of the section are the height of the modified centreline portion, the downstream slope and the upstream contact slope between the fill and tailings.

The downstream slope will generally be dictated by the construction materials available, but the height of the modified centreline portion and the upstream contact slope will be a function of the seismicity of the site. The height of the modified centreline portion can be considered in terms of Critical Height ($H_c$), which is defined as that height at which the pseudo-static factor of safety is equal to 1.0 under a given acceleration. The relationships between $H_c$, acceleration and the upstream contact slope are shown on Figure 4, for a given set of assumptions and the loading conditions shown on Figure 3.

The concepts presented in Figure 4 can be used for an initial determination of $H_c$. However, it is important to realize that this critical height is not a limiting height and only defines the height at which the critical acceleration for the embankment section $k_c$, is equal to the design acceleration for the site, $a_{max}$. Higher embankments, with a value of $k_c$ less than $a_{max}$, can be safely designed but will be subject to some deformation during the earthquake shaking.

The modified centreline embankment must also incorporate suitable provisions for seepage control and for piping prevention. Since the embankment fill extends slightly over more compressible tailings materials, consolidation settlement may result in cracking of the embankment core zone. Therefore, the embankment design must incorporate suitable filter criteria and drainage provisions. In general, the tailings mass forms an ideal crack stopping filter medium so that piping failure is not a major consideration. Embankment stability can also be enhanced by incorporating drainage features such as chimney drains to reduce pore pressures within the structural zone of the embankment.

![Diagram showing the relationship between critical height and acceleration](image)

**Figure 4** Relationship between critical height and acceleration
Upstream Stability

Upstream stability needs to consider two critical loading conditions: short-term loading on the tailings beach during embankment crest raising; and post-seismic upstream stability when the tailings would have only post liquefaction residual strength. In the first case, the principal concern is safety, whereas for the second case the principal concern is for failures causing loss of freeboard. Both cases need to be analyzed to determine the maximum allowable freeboard, which can then be related to flood storage requirements (Figure 5). In both analyses the appropriate strength characteristics of the tailings need to be known, in addition to those of the embankment fill materials.

\[ \frac{c_u}{\rho'} = 0.2 - 0.3 \]

(i) Short term construction.
Tailings strength, \( \frac{c_u}{\rho'} = 0.2 - 0.3 \)

\[ \frac{c_u}{\rho'} = 0.1 - 0.2 \]

(ii) Post earthquake loss of freeboard.
Tailings residual strength, \( \frac{c_u}{\rho'} = 0.1 - 0.2 \)

Figure 5 Upstream stability loading cases to determine maximum freeboard

Deformation Analyses

Deformation analyses can be carried out using simplified procedures of Newmark [2] and Makdisi and Seed[3]. The analyses compare the critical acceleration \( k_c \) with the site design acceleration, \( a_{max} \), and compute displacements using empirical relationships and case history data from conventional water retaining dams. Modification of the amplitude of the ground acceleration as it propagates up through the embankment can be determined using the SHAKE [4] program. Similarly, the value of \( k_c \) at any elevation in the embankment can be determined from standard stability analysis programs. In order to compensate for the geometry of the modified centreline embankment and uncertainties in the mode of deformation, the largest value of acceleration determined from SHAKE can be used together with the smallest value of \( k_c \) to compute potential deformations.

A pseudo-dynamic finite element displacement analysis has been developed by Byrne et al [5,6]. This analysis can be used to determine deformations under both upstream and downstream earthquake loading, and to define the location and magnitude of the largest deformations. In general it predicts deformations somewhat larger than those from the simplified Newmark analyses using the extreme values.

The stability analyses discussed above have only considered the most extreme loading conditions. In all embankment designs, all loading cases must be analyzed using relevant material parameters to ensure that acceptable factors of safety exist for each loading case.

4. Case Histories

Montana Tunnels Mine, Montana, USA.

The Montana Tunnels Mine is an open pit operation which involves processing gold, lead, zinc and silver ore at a rate of approximately 13,700 tonnes per day. The mine has been operating since 1987. Total mineable reserves from inception of mining have recently been expanded from 38 to 62 million tonnes.

The original tailings embankment was designed using a downstream method of construction for the annual staged expansions[7]. The compacted rockfill embankment layout was modified in 1990, when ongoing expansions were constructed using the modified centreline method in order to minimize fill quantities and preserve a downstream process water pond[8]. The modified centreline section was changed again in 1993 to enable expansion of the tailings impoundment to provide storage for the increased ore reserves. The embankment is presently designed to reach a maximum ultimate height of 105 metres. A schematic cross-section through the embankment is shown on Figure 6.

The redesign of the modified centreline embankment in 1993 included an extensive site investigation program which incorporated drilling, sampling, standard penetration testing, seismic piezocone testwork and installation of vibrating wire piezometers. A line of wick drains was installed along the tailings beach to enhance drainage into the free-draining embankment. A second wick drain program[9] was also completed within the tailings impoundment to dissipate excess pore pressures, accelerate consolidation and enhance seismic stability.

The stability assessment for the embankment included conventional limit equilibrium analyses for static, pseudo-static and post-earthquake conditions. Additional pseudo-dynamic finite element analyses, using the procedure described by Byrne et al[5], were also used to evaluate potential embankment deformations for a maximum credible earthquake with a peak horizontal ground acceleration of 0.22 g. The analysis includes both the inertia forces from the earthquake as well as the softening effect of the soil during cyclic loading. The fifth modified centreline embankment raise will be completed at the Montana Tunnels Mine during 1994, with annual expansions planned through 2001.
Kensington Venture, Alaska, USA

The Kensington Project is a proposed underground gold mine located 40 miles north of Juneau, Alaska, on the east side of the Lynn Canal. The mine will require construction of a 89 metre high dam to contain the tailings from the mining operations. The dam is to be constructed in stages using compacted earthfill and rockfill and a modified centrel ine arrangement. The project is located in an area of high potential seismicity and earthquake-induced liquefaction of the tailings is possible. The stability of the top portion of the dam and the potential displacements resulting from earthquake loading are therefore of extreme importance. A cross-section through the proposed final embankment is shown on Figure 7.

Conventional limit equilibrium and Newmark analyses, including hydrodynamic loading from the liquefied tailings, indicate that the embankment is stable and deformations would be very small. Deformation analyses were also carried out using the pseudo-dynamic finite element procedure developed by Byrne et al [5]. The analysis allows both the inertia forces from the earthquake as well as the softening effect of the liquefied soil to be considered.

Peak horizontal ground accelerations ranging from 0.2 g to 0.6 g were considered with corresponding peak ground velocities of 0.2 and 0.6 metre/second. The predicted peak displacements of the crest of the dam are 0.48 metre horizontal and 0.09 metre vertical. The maximum movement of the dam predicted from the Newmark analysis using the same soil strengths was 0.14 metres.

The Kensington Venture is currently in the final stages of permitting.
Kemess South Project, B.C., Canada
The Kemess South Project, situated in north central British Columbia, is presently in the final stages of permitting and is scheduled for development in 1995. A total reserve of 220 million tonnes of gold and copper ore will be processed at a rate of 40,000 tonnes per day. The project will include the staged construction of a compacted earthfill tailings embankment using the modified centrelne technique to an ultimate height of 150 metres. A schematic embankment section is shown on Figure 8.

The project site is situated in an area of low seismicity and conventional pseudo-static limit equilibrium analyses indicate an adequate factor of safety against embankment deformation. The modified centrelne embankment section was selected in order to minimize the quantity of fill required for staged expansions, and thus reduce on-going capital expenditures. Also, the downstream face of the embankment will be incrementally revegetated to minimize environmental impacts during operations and to reduce post-closure reclamation requirements.

5. Conclusions

The modified centrelne embankment provides the least cost compacted fill embankment for tailings storage facilities in areas of high seismicity and for low strength tailings. These embankments are intrinsically stable under earthquake loading even with the tailings fully liquifed. They can be constructed in stages using standard mining equipment and overburden materials from on-going mining operations. After the initial one or two stages no further construction is required on the downstream face, which allows for on-going reclamation during operations.

The modified centrelne design has been successfully implemented at the Montana Tunnels Mine in Montana, where a final embankment height of over 100 metres is planned. A detailed design has been developed for the Kensington Venture in Alaska and is in the final stages of the review process. Designs for new projects in B.C. and elsewhere in North America are currently at the development stage.
